29th August 2016

## Basics: Universal Hashing

Basic tool for shuffling and sampling from any set of objects

$O = \{1, 2, \dots, n\}$ .

- $h : O \rightarrow \{1, 2, \dots, m\}$
- $Pr(h(x) = h(y)) \leq \frac{1}{m}$  iff  $x \neq y$ .

Some implementations

- Pick a random number  $a$  and  $b$ , a large enough prime, return  $h(x) = ax + b \bmod p \bmod m$
- **Fastest Trick:** Choose  $m = 2^M$  to be power of 2, choose a random odd integer return  $h(x) = ax \gg (32 - M)$

Problems:

- Given a set  $O$ , randomly assign it to  $m$  bins.
- Randomly sample  $1/m$  fraction of the data.
- **Activity:** Suppose  $m \gg n$  How to sample one element randomly from  $O$

## Bloom Filters Set Up

**A common Task:** How to know whether some event occurred (before) or not without storing the event information? The number of possible events are huge. The following list is from Wikipedia

- Akamai web servers use Bloom filters to prevent "one-hit-wonders" from being stored in its disk caches. One-hit-wonders are web objects requested by users just once.
- Google BigTable, Apache HBase and Apache Cassandra, and Postgresql use Bloom filters to reduce the disk lookups for non-existent rows or columns. Avoiding costly disk lookups considerably increases the performance of a database query operation.
- The Google Chrome web browser used to use a Bloom filter to identify malicious URLs.
- The Squid Web Proxy Cache uses Bloom filters for cache digests
- Bitcoin uses Bloom filters to speed up wallet synchronization.
- many more.

# The Bloom Filter Algorithm and Analysis

A Dynamic Data Structure of  $m$  bit arrays  $B$

- Pick  $k$  universal hash function  $h_i : O \rightarrow \{1, 2, \dots, m\}$   
 $i \in \{1, 2, \dots, k\}$ .
- **Insert**  $o_j$ : Set all the bits  $B(h_i(o_j)) = 1. \forall i \in \{1, 2, \dots, k\}$
- **Query**  $o_j$ : If  $B(h_i(o_j)) = 1 \forall i \in \{1, 2, \dots, k\}$  RETURN True ELSE false

Properties

- If an item is present, the algorithm is always correct. No false negative.
- If an item is not present, the algorithm may return true with small probability.
- Cannot delete items easily.

Analysis On-Board

# Generalized Bloom Filters: Count-Min Sketch

On a network, a lot of events keep happening. Cannot afford to store event information.

- **Bloom Filters:** Keep track of whether an given event has already happened or not.
- **Count Min Sketches (or Count Sketches):** Keep track of the frequency of the frequent events (heavy hitters).
  - Instead of bits keep Counters
  - Usually, to avoid collisions among different hashes, they are hashed into different arrays. (Hence we get Matrix)

# The Classical (Non-Adaptive) Approximate Counting:

## Setting:

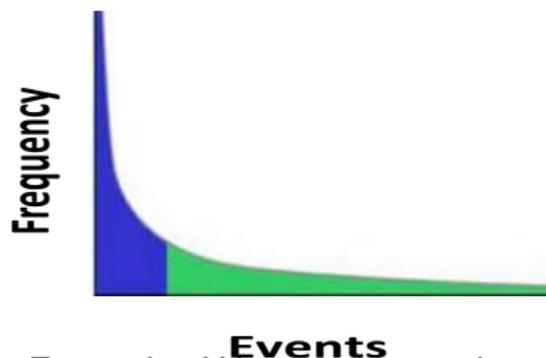

- We are given a huge number of items (co-variate)  $i \in I$  to track over time  $t \in \{1, 2, \dots, T\}$ .  $T$  can be large as well.
- We only see increments  $(i, t, v)$ , the increment  $v$  to item  $i$  at time  $t$ .

**Goal:** In limited space (hopefully  $O(\log |I| \times T)$ ), we want to

- **Point Queries:** Estimate the counts (increments) of item  $i$  at time  $t$ .
- **Range Queries:** Estimate the counts (increments) of item  $i$  during the given range  $[t_1, t_2]$ .

**Classical Sketching:** Count-Sketch, Count-Min Sketch (CMS), Lossy Counting, etc.

# Idea: Power Law Everywhere in Practice

- Example: We want to cache answers to frequent queries on a server. All queries are just too much to keep track of.
- How to identify very frequent queries? (Note, we cannot count everything.)
- We don't even know which ones are frequent, we only see some queries within a given time set.

# Counting Heavy Hitters on Data Streams

**Real Problem:** How to identify significant event (frequent) without having to count all of them. (sub-linear)

# Counting Heavy Hitters on Data Streams

**Real Problem:** How to identify significant event (frequent) without having to count all of them. (sub-linear)

## Classical Formalism (Turnstile Model)

- Assume we have a very long vector  $v$  (Dim  $D$ ), we cannot materialize.
- We only see increments to its coordinates. E.g. co-ordinate  $i$  is incremented by 10 at time  $t$ .
- **Goal:** Find  $s$  heaviest coordinate, using space  $k \ll D$

# Counting Heavy Hitters on Data Streams

**Real Problem:** How to identify significant event (frequent) without having to count all of them. (sub-linear)

## Classical Formalism (Turnstile Model)

- Assume we have a very long vector  $v$  (Dim  $D$ ), we cannot materialize.
- We only see increments to its coordinates. E.g. co-ordinate  $i$  is incremented by 10 at time  $t$ .
- **Goal:** Find  $s$  heaviest coordinate, using space  $k \ll D$

**Seems Hopeless !**

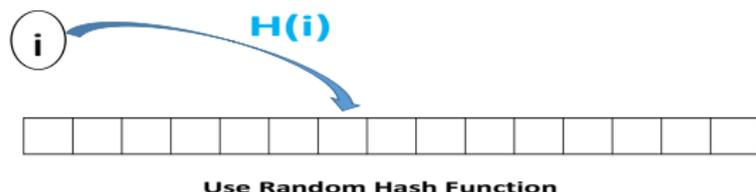

**Uncertainty is the Refuge of Hope.**

—Henri Frederic Amiel (1821-81)

## Basic Idea behind Sketching.

Randomly assign items to a small number of counters.

- It works! AMS 85, Moody 89, Charikar 99, MuthuKrishnana 02, etc.
- If no collisions, counts exact.

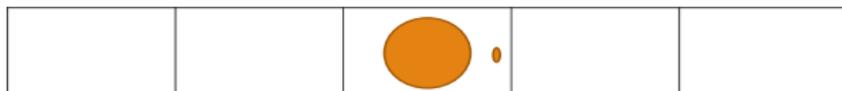

### Handling Time:

- Treat each pair  $(i, t)$  (item, time) as different item.
- Hash pairs  $(i, t)$ , instead of just items.
- Time only increases the number of items to  $|I| \times T$ .

# What happens during Collision ?

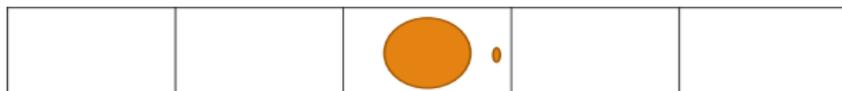

**The Good**

**We typically care about heavy hitters.**

# What happens during Collision ?

**The Good**

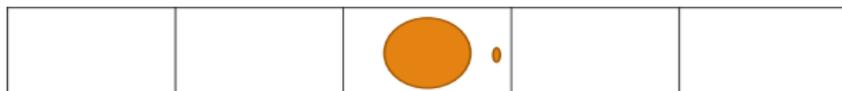

**The Irrelevant**

**We typically care about heavy hitters.**

# What happens during Collision ?

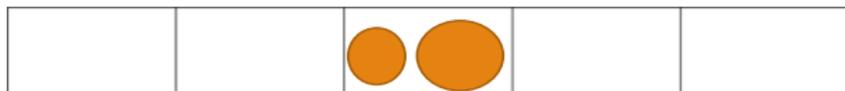

**The Good**

**The Irrelevant**

**The Unlucky**

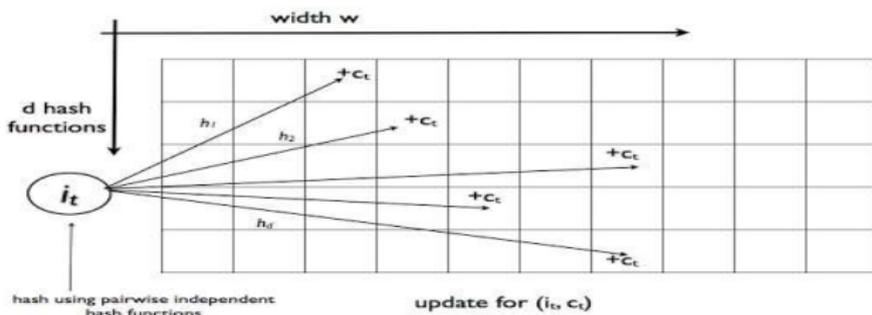

**We typically care about heavy hitters.**

# Maximizing Luck : Count-Min Sketch (CMS)

## Idea:

- We always overestimate, if unlucky, by a lot.
- Repeat independently  $d$  times and take minimum of all overestimates.
- Unless unlucky all  $d$  times, it will work. ( $d = \log \frac{1}{\delta}$ ,  $w = \frac{1}{\epsilon}$ )

## Theoretical Guarantee

- $c \leq \hat{c} \leq c + \epsilon \mathcal{M}^T$  with probability  $1 - \delta$ , where  $\mathcal{M}^T$  is sum of all counts in the stream.
- Space  $O(\log |I| \times T)$

# New Requirement: Time Adaptability

## In Practice:

- Recent trends are more important.
- A burst in the number of clicks in the past few minutes more informative than similar burst last month.

## Expectation: Time Adaptive Counting.

- Classical sketches do not take temporal effect into consideration.
- **Smart Tradeoff:** Given the same space, trade errors of recent counts with that of older ones.
- Like our memory, forget slowly.

# Existing Solution: Hokusai<sup>1</sup>

$$\mathbf{t} = \mathbf{T} (\mathbf{A}^T)$$

$$\mathbf{t} = \mathbf{T-1} (\mathbf{A}^{T-1})$$

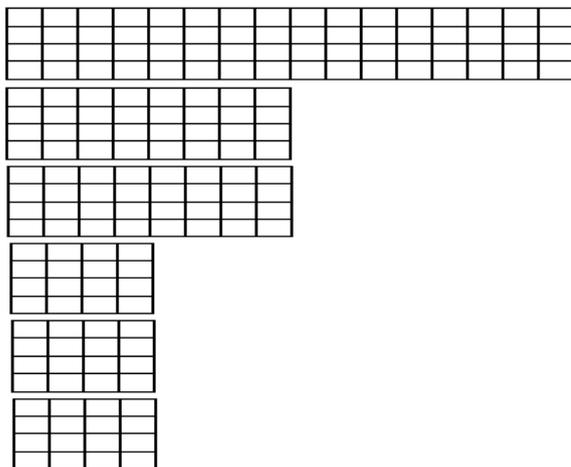

$$\mathbf{t} = \mathbf{T-2} (\mathbf{A}^{T-2})$$

$$\mathbf{t} = \mathbf{T-3} (\mathbf{A}^{T-3})$$

$$\mathbf{t} = \mathbf{T-4} (\mathbf{A}^{T-4})$$

$$\mathbf{t} = \mathbf{T-5} (\mathbf{A}^{T-5})$$

$$\mathbf{t} = \mathbf{T-6} (\mathbf{A}^{T-6})$$

**Idea:** Disproportionate allocation over time.

- Accuracy of CMS dependent on memory allocated.
- More space for recent sketches and less for older.
- Keep a CMS sketch for every time. Shrink sketch size on fly.

**Clever Idea:** Exploit Rollover.

<sup>1</sup>Matusevych, Smola and Ahmad 2012

**Clever Idea:** Exploit Rollover.

<sup>1</sup>Matusevych, Smola and Ahmad 2012

# Problems with Hokusai

## Issues:

- Discontinuity. If time  $t$  is empty, we still have to shrink sketch size for older times.
- $O(T)$  memory. One for each  $t$ .
- Shrinking overhead. Shrink  $\log t$  sketches for every transition from  $t$  to  $t + 1$ .
- No flexibility.

# Detour: Dolby Noise Reduction (1960s)

## High Level View

- In digital recording, the music signal compete with tape hiss (background noise).
- if Signal to Noise (SNR) ratio is high, the recording is noise free.
- While recording the frequencies in the music is artificially inflated (Pre-Emphasis).
- During playback a reverse transformation is applied which cancels pre-emphasis. (De-Emphasis)
- Overall effect of noise is minimized.

# Proposal: (Adaptive)Ada-Sketches

## Analogy with Dolby Noise Reduction:

- Sketches preserves heavier counts more accurately.
- Artificially inflate recent counts (Pre-emphasis).
- Inflated counts will be preserved with less error.
- Deflate by exact same amount during estimation. (De-emphasis)

# Proposal: (Adaptive)Ada-Sketches

## Analogy with Dolby Noise Reduction:

- Sketches preserves heavier counts more accurately.
- Artificially inflate recent counts (Pre-emphasis).
- Inflated counts will be preserved with less error.
- Deflate by exact same amount during estimation. (De-emphasis)

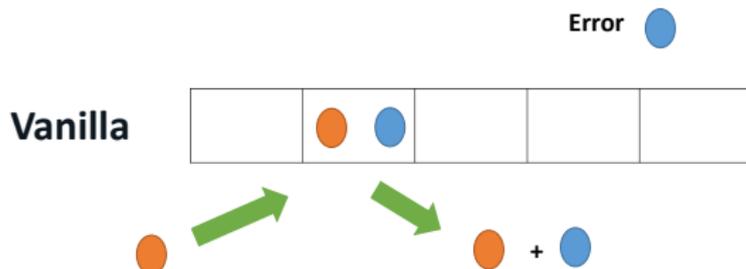

## Proposal

- Let  $f(t)$  be any (pre-defined) monotonically increasing sequence. ( $f(t)$  can be chosen wisely)
- Multiply the count of  $(i, t)$  with  $f(t)$  and then add to the sketch.
- While querying  $(i, t)$ , get the estimate and divide by  $f(t)$

# Why it works ?

## Observation

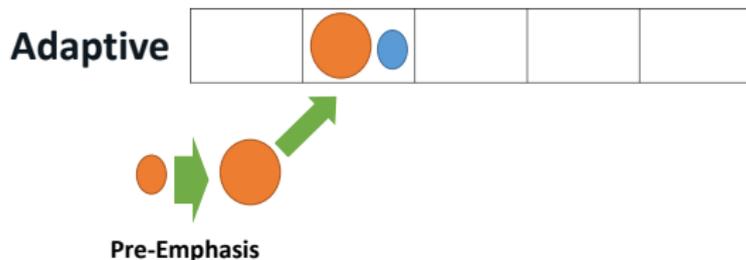

- If no collision then exact.
- During collision, errors or recent counts decrease due to greater de-emphasis.

# Why it works ?

## Observation

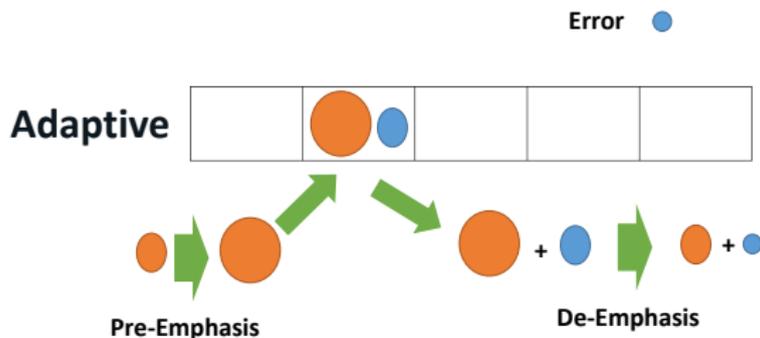

- If no collision then exact.
- During collision, errors or recent counts decrease due to greater de-emphasis.

# Why it works ?

## Observation

- If no collision then exact.
- During collision, errors or recent counts decrease due to greater de-emphasis.

# Advantages

- No Discontinuity. If time  $t$  is empty, no addition, no extra collisions, no extra errors.
- $O(\log |I| \times T)$  memory just like CMS.
- No shrinking overhead. Minimum modification to CMS. (Strict Generalization)

## Provable Time Adaptive Guarantees

### Theorem

For  $w = \lceil \frac{\epsilon}{\delta} \rceil$  and  $d = \log \frac{1}{\delta}$ , given any  $(i, t)$  we have

$$c_i^t \leq \hat{c}_i^t \leq c_i^t + \epsilon \beta^t \sqrt{\mathcal{M}_2^T}$$

with probability  $1 - \delta$ . Here  $\beta^t = \frac{\sqrt{\sum_{t'=0}^T (f(t'))^2}}{f(t)}$  is the time adaptive factor monotonically decreasing with  $t$ .

More..

## Works with any Sketching Algorithm

- Adaptive Count Sketches, Adaptive Lossy Counting etc.
- Provable Time Adaptive Guarantees for all of them.

## Works with any Sketching Algorithm

- Adaptive Count Sketches, Adaptive Lossy Counting etc.
- Provable Time Adaptive Guarantees for all of them.

## Flexibility in Choice of $f(t)$

- Any monotonic  $f(t)$  works. Can be tailored
- Upper bound dependent on  $\beta^t = \frac{\sqrt{\sum_{t'=0}^T (f(t'))^2}}{f(t)}$ .
- Fine control over the error distributions.
