Abstract. There has been a major emphasis recently in the semiconductor industry on designing industrial-strength property specification languages (PSLs). Two major languages are ForSpec and Sugar 2.0, which are both extensions of Pnueli's LTL. Both ForSpec and Sugar 2.0 directly support reset/abort signals, in which a check for a property ψ may be terminated and declared successful by an reset/abort signal, provided the check has not yet failed. ForSpec and Sugar 2.0, however, differ in their definition of failure. The definition of failure in ForSpec is syntactic, while the definition in Sugar 2.0 is semantic. In this work we examine the implications of this distinction between the two approaches, which we refer to as the *reset* approach (for ForSpec) and the *abort* approach (for Sugar 2.0). In order to focus on the reset/abort issue, we do not consider the full languages, which are quite rich, but rather the extensions of LTL with the reset/abort constructs.

We show that the distinction between syntactic and semantic failure has a dramatic impact on the complexity of using the language in a model-checking tool. We prove that Reset-LTL enjoys the "fast-compilation property": there is a linear translation of Reset-LTL formulas into alternating Büchi automata, which implies a linear translation of Reset-LTL formulas into a symbolic representation of nondeterministic Büchi automata. In contrast, the translation of Abort-LTL formulas into alternating Büchi automata is nonelementary (i.e., cannot be bounded by a stack of exponentials of a bounded height); each abort yields an exponential blow-up in the translation. This complexity bounds also apply to model checking; model checking Reset-LTL formulas is exponential in the size of the property, while model checking Abort-LTL formulas is nonelementary in the size of the property (the same bounds apply to satisfiability checking).

1 Introduction

A key issue in the design of a model-checking tool is the choice of the formal specification language used to specify properties, as this language is one of the *primary* interfaces to the tool [8]. (The other primary interface is the modelling language, which is typically the hardware description language used by the designers). In view of this, there has been a major emphasis recently in the semiconductor industry on designing industrial-strength property specification languages (PSLs), e.g., Cadence's FormalCheck Specification Language [9], Intel's ForSpec [1][4], IBM's Sugar 2.0 [2][5], and Verisity's Temporal ***e*** [12]. These languages are all *linear* temporal languages (Sugar 2.0 has also a branching-time extension), in which time is treated as if each moment in time has a unique possible future. Thus, linear temporal formulas are interpreted over linear sequences, and we regard them as describing the behavior of a single computation of a system. In particular, both ForSpec and Sugar 2.0 can be viewed as extensions of Pnueli's LTL [14], with regular connectives and hardware-oriented features.

[4] ForSpec 2.0 has been designed in a collaboration between Intel, Co-Design Automation, Synopsys, and Verisity, and has been incorporated into the hardware verification language Open Vera, see `http://www.open-vera.com`.

[5] See `http://www.haifa.il.ibm.com/projects/verification/sugar/` for description of Sugar 2.0.

The regular connectives are aimed at giving the language the full expressive power of Büchi automata (cf. [1]). In contrast, the hardware-oriented features, *clocks* and *resets/aborts*, are aimed at offering direct support to two specification modes often used by verification engineers in the semiconductor industry. Both clocks and reset/abort are features that are needed to address the fact that modern semiconductor designs consists of interacting parallel modules. Today's semiconductor design technology is still dominated by synchronous design methodology. In synchronous circuits, clock signals synchronize the sequential logic, providing the designer with a simple operational model. While the asynchronous approach holds the promise of greater speed ([6]), designing asynchronous circuits is significantly harder than designing synchronous circuits. Current design methodology attempt to strike a compromise between the two approaches by using multiple clocks. This methodology results in architectures that are globally asynchronous but locally synchronous. ForSpec, for example, supports local asynchrony via the concept of *local clocks*, which enables each subformula to sample the trace according to a different clock; Sugar 2.0 supports local clocks in a similar way.

Another aspect of the fact that modern designs consist of interacting parallel modules is the fact that a process running on one module can be reset by a signal coming from another module. As noted in [16], reset control has long been a critical aspect of embedded control design. Both ForSpec and Sugar 2.0 directly support reset/abort signals. The ForSpec formula "accept a in ψ" asserts that the property ψ should be checked only until the arrival of the reset signal a, at which point the check is considered to have *succeeded*. Similarly, the Sugar 2.0 formula "ψ abort on a" asserts that property ψ should be checked only until the arrival of the abort signal a, at which point the check is considered to have succeeded. In both ForSpec and Sugar 2.0 the signal a has to arrive before the property ψ has "failed"; arrival after failure cannot "rescue" ψ. ForSpec and Sugar 2.0, however, differ in their definition of *failure*.

The definition of failure in Sugar 2.0 is semantic; a formula fails at a point in a trace if the prefix up to (and including) that point cannot be extended in a manner that satisfies the formula. For example, the formula " next **false**" fails semantically at time 0, because it is impossible to extend the point at time 0 to a trace that satisfies the formula. In contrast, the definition of failure in ForSpec is syntactic. Thus, " next **false**" fails syntactically at time 1, because it is only then that the failure is actually discovered. As another example, consider the formula "(globally $\neg p$) $\wedge$ (eventually p)". It fails semantically at time 0, but it never fails syntactically, since it is always possible to wait longer for the satisfaction of the eventuality (Formally, the notion of syntactic failure correspond to the notion of *informative prefix* in [7].) Mathematically, the definition of semantic failure is significantly simpler than that of syntactic failure (see formal definitions in the sequel), since the latter requires an inductive definition with respect to all syntactical constructs in the language. In this work we examine the implications of this distinction between the two approaches, which we refer as the *reset* approach (for ForSpec) and the *abort* approach (for Sugar 2.0). In order to focus on the reset/abort issue, we do not consider the full languages, which are quite rich, but rather the extensions of LTL with the reset/abort constructs.

We show that the distinction between syntactic and semantic failure has a dramatic impact on the complexity of using the language in a model-checking tool. In linear-time model checking we are given a design M (expressed in an HDL) and a property ψ (expressed in a PSL). To check that M satisfies ψ we construct a state-transition system T_M that corresponds to M and a nondeterministic Büchi automaton $\mathcal{A}_{\neg\psi}$ that corresponds to the negation of ψ. We then check if the composition $T_M||\mathcal{A}_{\neg\psi}$ contains a reachable fair cycle, which represents a trace of M falsifying ψ [19]. In a symbolic model checker the construction of T_M is linear in the size of M [3]. For LTL, the construction of $\mathcal{A}_{\neg\psi}$ is also linear in the size of ψ [3, 18]. Thus, the front end of a model checker is quite fast; it is the back end, which has to search for a reachable fair cycle in $T_M||\mathcal{A}_{\neg\psi}$, that suffers from the "state-explosion problem".

We show here that Reset-LTL enjoys that "fast-compilation property": there is a linear translation of Reset-LTL formulas into alternating Büchi automata, which are exponentially more succinct than nondeterministic Büchi automata [18]. This implies a linear translation of Reset-LTL formulas into a symbolic representation of nondeterministic Büchi automata. In contrast, the translation of Abort-LTL formulas into alternating Büchi automata is nonelementary (i.e., cannot be bounded by a stack of exponentials of a bounded height); each abort yields an exponential blow-up in the translation. These complexity bounds are also shown to apply to model checking; model checking Reset-LTL formulas is exponential in the size of the property, while model checking Abort-LTL formulas is nonelementary in the size of the property (the same bounds apply to satisfiability checking).

Our results provide a rationale for the syntactic flavor of defining failure in ForSpec; it is this syntactic flavor that enables alternating automata to check for failure. This approach has a more operational flavor, which could be argued to match closer the intuition of verification engineers. In contrast, alternating automata cannot check for semantic failures, since these requires coordination between independent branches of alternating runs. It is this coordination that yields an exponential blow-up per abort. Our lower bounds for model checking and satisfiability show that this blow-up is intrinsic and not a side-effect of the automata-theoretic approach.

2 Preliminaries

A *nondeterministic Büchi word automaton* (NBW) is $\mathcal{A} = \langle \Sigma, S, S_0, \delta, F \rangle$, where Σ is a finite set of alphabet letters, S is a set of states, $\delta : S \times \Sigma \to 2^S$ is a transition function, $S_0 \subseteq S$ is a set of initial states, and $F \subseteq S$ is a set of accepting states. Let $w = w_0, w_1, \ldots$ be an infinite word over Σ. For $i \in \mathbb{N}$, let $w^i = w_i, w_{i+1}, \ldots$ denote the suffix of w from its ith letter. A sequence $\rho = s_0, s_1, \ldots$ in S^ω is a *run* of $\mathcal{A}$ over an infinite word $w \in \Sigma^\omega$, if $s_0 \in S_0$ and for every $i > 0$, we have $s_{i+1} \in \delta(s_i, w_i)$. We use $inf(\rho)$ to denote the set of states that appear infinitely often in ρ. A run ρ of $\mathcal{A}$ is *accepting* if $inf(\rho) \cap F \neq \emptyset$. An NBW $\mathcal{A}$ accepts a word w if $\mathcal{A}$ has an accepting run over w. We use $L(\mathcal{A})$ to denote the set of words that are accepted by $\mathcal{A}$. For $s \in S$, we denote by $\mathcal{A}^s$ the automaton $\mathcal{A}$ with a single initial state s.

Before we define an alternating Büchi word automaton, we need the following definition. For a given set X, let $\mathcal{B}^+(X)$ be the set of positive Boolean formulas over X (i.e., Boolean formulas built from elements in X using $\wedge$ and $\vee$), where we also allow the formulas **true** and **false**. Let $Y \subseteq X$. We say that Y *satisfies* a formula $\theta \in \mathcal{B}^+(X)$ if the truth assignment that assigns *true* to the members of Y and assigns *false* to the members of $X \setminus Y$ satisfies θ.

An *alternating Büchi word automaton* (ABW) is $\mathcal{A} = \langle \Sigma, S, s^0, \delta, F \rangle$, where Σ, S, and F are as in NBW, $s^0 \in S$ is a single initial state, and $\delta : S \times \Sigma \to \mathcal{B}^+(S)$ is a transition function. A run of $\mathcal{A}$ on an infinite word $w = w_0, w_1, \ldots$ is a (possibly infinite) S-labelled tree τ such that $\tau(\varepsilon) = s^0$ and the following holds: if $|x| = i$, $\tau(x) = s$, and $\delta(s, w_i) = \theta$, then x has k children $x_1, \ldots, x_k$, for some $k \leq |S|$, and $\{\tau(x1), \ldots, \tau(xk)\}$ satisfies θ. The run τ is *accepting* if every infinite branch in τ includes infinitely many labels in F. Note that the run can also have finite branches; if $|x| = i$, $\tau(x) = s$, and $\delta(s, a_i) = \mathbf{true}$, then x need not have children.

An *alternating weak word automaton* (*AWW*) is an ABW such that for every strongly connected component C of the automaton, either $C \subseteq F$ or $C \cap F = \emptyset$. Given two AWW $\mathcal{A}_1$ and $\mathcal{A}_2$, we can construct AWW for $\Sigma^\omega \setminus L(\mathcal{A}_1)$, $L(\mathcal{A}_1) \cap L(\mathcal{A}_2)$, and $L(\mathcal{A}_1) \cup L(\mathcal{A}_2)$, which are linear in their size, relative to $\mathcal{A}_1$ and $\mathcal{A}_2$ [13].

Next, we define the temporal logic LTL over a set of atomic propositions AP. The syntax of LTL is as follows. An atom $p \in AP$ is a formula. If ψ_1 and ψ_2 are LTL formulas, then so are $\neg\psi_1$, $\psi_1 \wedge \psi_2$, $\psi_1 \vee \psi_2$, $\mathbf{X}\,\psi_1$, and $\psi_1\ \mathbf{U}\ \psi_2$. For the semantics of LTL see [14]. Each LTL formula ψ induces a language $L(\psi) \subseteq (2^{AP})^\omega$ of exactly all the infinite words that satisfy ψ.

Theorem 1. [18] *For every* LTL *formula* ψ*, there exists an AWW* $\mathcal{A}_\psi$ *with* $O(|\psi|)$ *states such that* $L(\psi) = L(\mathcal{A}_\psi)$.

Proof. For every subformula φ of ψ, we construct an AWW $\mathcal{A}_\varphi$ for φ. The construction proceeds inductively as follows.

- For $\varphi = p \in AP$, we define $\mathcal{A}_p = \langle 2^{AP}, \{s_p^0\}, s_p^0, \delta_p, \emptyset \rangle$, where $\delta_p(s_p^0, \sigma) =$ **true** if p is true in σ and $\delta_p(s_p^0, \sigma) =$ **false** otherwise.
- Let ψ_1 and ψ_2 be subformulas of ψ and let $\mathcal{A}_{\psi_1}$ and $\mathcal{A}_{\psi_2}$ the automata for these formulas. The automata for $\neg\psi_1$, $\psi_1 \wedge \psi_2$, and $\psi_1 \vee \psi_2$ are the automata for $\Sigma^\omega \setminus L(\mathcal{A}_1)$, $L(\mathcal{A}_1) \cap L(\mathcal{A}_2)$, and $L(\mathcal{A}_1) \cup L(\mathcal{A}_2)$, respectively.
- For $\varphi = \mathbf{X}\,\psi_1$, we define $\mathcal{A}_\varphi = \langle 2^{AP}, \{s_\varphi^0\} \cup S_{\psi_1}, s_\varphi^0, \delta_0 \cup \delta_{\psi_1}, F_{\psi_1} \rangle$ where $\delta_0(s_\varphi^0, \sigma) = s_{\psi_1}^0$.
- For $\varphi = \psi_1\,\mathbf{U}\,\psi_2$, we define $\mathcal{A}_\varphi = \langle 2^{AP}, \{s_\varphi^0\} \cup S_{\psi_1} \cup S_{\psi_2}, s_\varphi^0, \delta_0 \cup \delta_{\psi_1} \cup \delta_{\psi_2}, F_{\psi_1} \cup F_{\psi_2} \rangle$ where $\delta_0(s_\varphi^0, \sigma) = \delta_{\psi_2}(s_{\psi_2}^0, \sigma) \vee (\delta_{\psi_1}(s_{\psi_1}^0, \sigma) \wedge s_\varphi^0)$.

An automata-theoretic approach for LTL satisfiability and model-checking is presented in [20, 21]. The approach is based on a construction of NBW for LTL formulas. Given an LTL formula ψ, satisfiability of ψ can be checked by first constructing an NBW $\mathcal{A}_\psi$ for ψ and then checking if $L(\mathcal{A}_\psi)$ is empty. As for model checking, assume that we want to check whether a system that is modelled by an NBW $\mathcal{A}_M$ satisfies ψ. First construct an NBW $\mathcal{A}_{\neg\psi}$ for $\neg\psi$, then check whether $L(\mathcal{A}_M) \cap L(\mathcal{A}_{\neg\psi}) = \emptyset$. (The automaton $\mathcal{A}_{\neg\psi}$ can also be used as a run-time monitor to check that ψ does not fail during a simulation run [7].)

Following [18], given an LTL formula ψ, the construction of the NBW for ψ is done in two steps: (1) Construct an ABW $\mathcal{A}'_\psi$ that is linear in the size of ψ. (2) Translate $\mathcal{A}'_\psi$ to $\mathcal{A}_\psi$. The size of $\mathcal{A}_\psi$ is exponential in the size of $\mathcal{A}'_\psi$ [11], and hence also in the size of ψ. Since checking for emptiness for NBW can be done in linear time or in nondeterministic logarithmic space [21], both satisfiability and model checking can be solved in exponential time or in polynomial space. Since both problems are PSPACE-complete [15], the bound is tight.

3 Reset-LTL

In this section we define analyze the logic Reset-LTL. We show that for every Reset-LTL formula ψ, we can efficiently construct an ABW $\mathcal{A}_\psi$ that accepts $L(\psi)$. This construction allows us to apply the automata-theoretic approach presented in Section 2 to Reset-LTL.

Let ψ be a Reset-LTL formula over 2^{AP} and let b be a Boolean formula over AP. Then, accept b in ψ and reject b in ψ are Reset-LTL formulas. The semantic of Reset-LTL is defined with respect to tuples $\langle w, a, r \rangle$, where w is an infinite word over 2^{AP}, and a and r are Boolean formulas over AP. We refer to a and r as the *context* of the formula. Intuitively, a describes an *accept* signal, while r describes a *reject* signal. Note that every letter σ in w is in 2^{AP}, thus a and r are either true or false in σ. The semantic is defined as follows:

- For $p \in AP$, we have that $\langle w, a, r \rangle \models p$ if $w_0 \models a \vee (p \wedge \neg r)$.
- $\langle w, a, r \rangle \models \neg\psi$ if $\langle w, r, a \rangle \not\models \psi$.
- $\langle w, a, r \rangle \models \psi_1 \wedge \psi_2$ if $\langle w, a, r \rangle \models \psi_1$ and $\langle w, a, r \rangle \models \psi_2$.
- $\langle w, a, r \rangle \models \psi_1 \vee \psi_2$ if $\langle w, a, r \rangle \models \psi_1$ or $\langle w, a, r \rangle \models \psi_2$.
- $\langle w, a, r \rangle \models \mathbf{X}\,\psi$ if $w_0 \models a$ or ($\langle w^1, a, r \rangle \models \psi$ and $w_0 \not\models r$).
- $\langle w, a, r \rangle \models \psi_1\,\mathbf{U}\,\psi_2$ if there exists $k \geq 0$ such that $\langle w^k, a, r \rangle \models \psi_2$ and for every $0 \leq j < k$, we have $\langle w^j, a, r \rangle \models \psi_1$.
- $\langle w, a, r \rangle \models$ accept b in ψ if $\langle w, a \vee (b \wedge \neg r), r \rangle \models \psi$.
- $\langle w, a, r \rangle \models$ reject b in ψ if $\langle w, a, r \vee (b \wedge \neg a) \rangle \models \psi$.

An infinite word w satisfies a formula ψ if $\langle w, \mathbf{false}, \mathbf{false}\rangle \models \psi$. The definition ensures that a and r are always disjoint, i.e., there is no $\sigma \in 2^{AP}$ that satisfies both a and r. It can be shown that this semantics satisfies a natural duality property: $\neg$accept a in ψ is logically equivalent to reject b in $\neg\psi$. For a discussion of this semantics, see [1]. Its key feature is that a formula holds if the accept signal is asserted before the formula "failed". The notion of failure is syntax driven. For example, **X false** cannot fail before time 1, since checking **X false** at time 0 requires checking **false** at time 1.

We now present a translation of Reset-LTL formulas into ABW. Note, that the context that is computed during the evaluation of Reset-LTL formulas depends the part of the formula that "wraps" each subformula. Given a formula ψ, we define for each subformula φ of ψ two Boolean formulas $acc_\psi[\varphi]$ and $rej_\psi[\varphi]$ that represent the context of φ with respect to ψ.

Definition 1. *For a* Reset-LTL *formula ψ and a subformula φ of ψ, we define the* acceptance context of φ, *denoted $acc_\psi[\varphi]$, and the* rejection context of φ, *denoted $rej_\psi[\varphi]$. The definition is by induction over the structure of the formula in a top-down direction.*

- *If $\varphi = \psi$, then $acc_\psi[\varphi] =$ **false** and $rej_\psi[\varphi] =$ **false**.*
- *Otherwise, let ξ be the innermost subformula of ψ that has φ as a strict subformula.*
  - *If $\xi =$ accept b in φ, then $acc_\psi[\varphi] = acc_\psi[\xi] \vee (b \wedge \neg rej_\psi[\xi])$ and $rej_\psi[\varphi] = rej_\psi[\xi]$.*
  - *If $\xi =$ reject b in φ, then $acc_\psi[\varphi] = acc_\psi[\xi]$ and $rej_\psi[\varphi] = rej_\psi[\xi] \vee (b \wedge \neg acc_\psi[\xi])$.*
  - *If $\xi = \neg\varphi$, then $acc_\psi[\varphi] = rej_\psi[\xi]$ and $rej_\psi[\varphi] = acc_\psi[\xi]$.*
  - *In all other cases, $acc_\psi[\varphi] = acc_\psi[\xi]$ and $rej_\psi[\varphi] = rej_\psi[\xi]$.*

A naive representation of the $acc_\psi[\varphi]$ and $rej_\psi[\varphi]$ Boolean formulas can lead to an exponential blowup. This can be avoided by using pointers to subformulas instead of rewriting them. Note that two subformulas that are syntactically identical might have different contexts. E.g., for the formula $\psi =$ accept p_0 in $p_1 \vee$ accept p_2 in p_1, there are two subformulas of the form p_1 in ψ. For the left subformula we have $acc_\psi[p_1] = p_0$ and for the right subformula we have $acc_\psi[p_1] = p_2$.

Theorem 2. *For every* Reset-LTL *formula ψ, there exists an AWW $\mathcal{A}_\psi$ with $O(|\psi|)$ states such that $L(\psi) = L(\mathcal{A}_\psi)$.*

Proof. For every subformula φ of ψ, we construct an automaton $\mathcal{A}_{\psi,\varphi}$. The automaton $\mathcal{A}_{\psi,\varphi}$ accepts an infinite word w iff $\langle w, acc_\psi[\varphi], rej_\psi[\varphi]\rangle \models \varphi$. The automaton $\mathcal{A}_\psi$ is then $\mathcal{A}_{\psi,\psi}$. The construction of $\mathcal{A}_{\psi,\varphi}$ proceeds by induction on the structure of φ as follows.

- For $\varphi = p \in AP$, we define $\mathcal{A}_{\psi,p} = \langle 2^{AP}, \{s^0_p\}, s^0_p, \delta_p, \emptyset\rangle$, where $\delta_p(s^0_p, \sigma) =$ **true** if $acc_\psi[\varphi] \vee (p \wedge \neg rej_\psi[\varphi])$ is true in σ and $\delta_p(s^0_p, \sigma) =$ **false** otherwise.
- For Boolean connectives we apply the Boolean closure of AWW.
- For $\varphi = \mathbf{X}\,\psi_1$, we define $\mathcal{A}_{\psi,\varphi} = \langle 2^{AP}, \{s^0_\varphi\} \cup S_{\psi_1}, s^0_\varphi, \delta_0 \cup \delta_{\psi_1}, F_{\psi_1}\rangle$ where

$$\delta_0(s^0_\varphi, \sigma) = \begin{cases} \mathbf{true} & \text{if } \sigma \models acc_\psi[\varphi], \\ \mathbf{false} & \text{if } \sigma \models rej_\psi[\varphi], \\ s^0_{\psi_1} & \text{otherwise.} \end{cases}$$

- For $\varphi = \psi_1\,\mathbf{U}\,\psi_2$, we define $\mathcal{A}_{\psi,\varphi} = \langle 2^{AP}, \{s^0_\varphi\} \cup S_{\psi_1} \cup S_{\psi_2}, s^0_\varphi, \delta_0 \cup \delta_{\psi_1} \cup \delta_{\psi_2}, F_{\psi_1} \cup F_{\psi_2}\rangle$, where $\delta_0(s^0_\varphi, \sigma) = \delta_{\psi_2}(s^0_{\psi_2}, \sigma) \vee (\delta_{\psi_1}(s^0_{\psi_1}, \sigma) \wedge s^0_\varphi)$.
- For $\varphi =$ accept b in ψ_1 we define $\mathcal{A}_{\psi,\varphi} = \mathcal{A}_{\psi,\psi_1}$
- For $\varphi =$ reject b in ψ_1 we define $\mathcal{A}_{\psi,\varphi} = \mathcal{A}_{\psi,\psi_1}$

Note that $\mathcal{A}_{\psi,\varphi}$ depends not only on φ but also on $acc_\psi[\varphi]$ and $rej_\psi[\varphi]$, which depend on the part of ψ that "wraps" φ. Thus, for example, the automaton $\mathcal{A}_{\psi,\psi_1}$ we get for $\varphi =$ accept b in ψ_1 is different from the automaton $\mathcal{A}_{\psi,\psi_1}$ we get for $\varphi =$ reject b in ψ_1, and both automata depend on b. In Appendix A, we prove that $\mathcal{A}_{\psi,\varphi}$ indeed accepts an infinite word w iff $\langle w, acc_\psi[\varphi], rej_\psi[\varphi]\rangle \models \varphi$.

The construction of ABW for Reset-LTL formulas allows us to use the automata-theoretic approach presented in Section 2. Accordingly, we have the following (the lower bounds follow from the known bounds for LTL).

Theorem 3. *The satisfiability and model-checking problems of* Reset-LTL *are PSPACE-complete.*

Remark 1. Theorem 3 holds only for formulas that are represented as trees where very subformula of ψ has a unique occurrence. It does not hold in DAG representation where subformulas that are syntactically identical are unified. In this case one occurrence of a subformula could be related to many automata that differ in their context. Thus, the size of the automaton could be exponential in the length of the formula, and the complexity of the automata-approach is EXPSPACE. In Appendix A.2 we show an EXPSPACE lower bound for the satisfiability of Reset-LTL formulas that are represented as DAGs. Thus, the bounds are tight.

Remark 2. The translation described above for Reset-LTL formulas depends on the fact that the context of subformulas is syntactically determined. We can use this fact to rewrite Reset-LTL formulas into equivalent LTLformulas. In Appendix A.1 we show a translation from Reset-LTL to LTL, which is based on the definition of $acc[]$ and $rej[]$. This translation implies that Reset-LTL is expressively equivalent to LTL. The same argument can be applied to ForSpec. Thus, the accept/reject constructs simply offer specifiers a direct ability to specify reset control; they do not increase the expressive power of the language.

4 Abort-LTL

In this section we define and analyze the logic Abort − LTL. construction of AWW for Abort-LTL formulas with size nonelementary The logic extends LTL with an abort operator. Formally, if ψ is an Abort-LTL formula over 2^{AP} and b is a Boolean formula over AP, then ψ abort on b is an Abort-LTL formula. The semantic of the abort operator is defined as follows:

- $w \models \psi$ abort on b iff $w \models \psi$ or there is a prefix w' of w and an infinite word w'' such that b is true in the last letter of w' and $w' \cdot w'' \models \psi$.

For example, the formula "($\mathbf{G}\, p$) abort on b" is equivalent to the formula $(p\mathbf{U}(p \wedge b)) \vee \mathbf{G}\, p$. Thus, in addition to words that satisfy $\mathbf{G}\, p$, the formula is satisfied by words with a prefix that ends in a letter that satisfies b and in which p holds in every state. Such a prefix can be extended to an infinite word where $\mathbf{G}\, p$ holds, and thus the word satisfies the formula.

We describe a construction of AWW for Abort-LTL formulas. The construction involves a nonelementary blow-up. This implies nonelementary solutions for the satisfiability and model-checking problems, to which we later prove matching lower bounds. For two integers n and k, let $exp(1, n) = 2^n$ and $exp(k, n) = 2^{exp(k-1,n)}$. Thus, $exp(k, n)$ is a tower of k exponents, with n at the top.

Theorem 4. *For every* Abort-LTL *formula ψ of length n and* abort on *nesting depth k, there exists an AWW $\mathcal{A}_\psi$ with $exp(k, n)$ states such that $L(\psi) = L(\mathcal{A}_\psi)$.*

Proof. The construction of AWW for LTL presented in Theorem 1 is inductive. Thus, in order to extend it for Abort-LTL formulas, we need to construct, given b and an AWW $\mathcal{A}_\psi$ for ψ, an AWW $\mathcal{A}_\varphi$ for $\varphi = \psi$ abort on b. Once we construct $\mathcal{A}_\varphi$, the inductive construction is as described in Theorem 1. Given b and $\mathcal{A}_\psi$, we construct $\mathcal{A}_\varphi$ as follows.

– Let $\mathcal{A}_n = \langle 2^{AP}, S_n, s^{n0}, \delta_n, F_n \rangle$ be an NBW such that $L(\mathcal{A}_n) = L(\mathcal{A}_\psi)$. According to [11], $\mathcal{A}_n$ indeed has a single initial state and its size is exponential in $\mathcal{A}_\psi$.
– Let $\mathcal{A}'_n = \langle 2^{AP}, S'_n, s'^{n0}, \delta'_n, F'_n \rangle$ be the NBW obtained from $\mathcal{A}_n$ by removing all the states from which there are no accepting runs, i.e, all states s such that $L(\mathcal{A}^s_n) = \emptyset$.
– Let $\mathcal{A}_{fin} = \langle 2^{AP}, S'_n, s'^{n0}, \delta, \emptyset \rangle$, be an AWW where δ is defined, for all $s \in S$ and $\sigma \in \Sigma$ as follows.

$$\delta(s,\sigma) = \begin{cases} \textbf{true} & \text{if } \sigma \models b, \\ \bigvee_{t \in \delta_n(s,\sigma)} t & \text{otherwise.} \end{cases}$$

Thus, whenever $\mathcal{A}'_n$ reads a letter that satisfies b, the AWW accepts. Intuitively, $\mathcal{A}_{fin}$ accepts words that contain prefixes where b holds in the last letter and ψ has not yet "failed".
– We define $\mathcal{A}_\varphi$ to be the automaton for $L(\mathcal{A}_\psi) \cup L(\mathcal{A}_{fin})$. Note that since both $\mathcal{A}_\psi$ and $\mathcal{A}_{fin}$ are AWW, so is $\mathcal{A}_\varphi$. The automaton $\mathcal{A}_\varphi$ accepts a word w if either $\mathcal{A}_\psi$ has an accepting run over w, or if $\mathcal{A}'_n$ has a finite run over a prefix w' of w, which ends in a letter σ that satisfies b.

In Appendix B, we prove that the automaton $\mathcal{A}_\varphi$ accept $L(\varphi)$. For LTL, every operator increases the number of states of the automaton by one, making the overall construction linear. In contrast, here every abort on operator involves an exponential blow up in the size of the auotmaton. In the worst case, the size of $\mathcal{A}_\psi$ is $exp(k,n)$ where k is the nesting depth of the abort on operator and n is the length of the formula.

The construction of ABW for Abort-LTL formulas allows us to use the automata-theoretic approach presented in Section 2, implying nonelementary solutions to the satisfiability and model-checking problems for Abort-LTL.

Theorem 5. *The satisfiabilty and model-checking problems of* Abort-LTL *are in SPACE($exp(k,n)$), where n is the length of the specification and k is the nesting depth of* abort on .

We now prove matching lower bounds. We first prove that the nonelementary blow-up in the translation described in Theorem 4 cannot be avoided. This proves that the automata-theoretic approach to Abort-LTL has nonelementary cost. We construct infinitely many Abort-LTL formulas ψ^k_n such that every AWW that accept $L(\psi^k_n)$ is of size $exp(k,n)$. The formulas ψ^k_n, are constructed such that $L(\psi^k_n)$ is closely related to $\{ww\Sigma^\omega : |w| = exp(k,n)\}$. Intuitively, we use the abort on operator to require that every letter in the first word is identical to the letter at the same position in the next word. It is known that every AWW that accept this language has at least $exp(k,n)$ states. The proof that every AWW that accepts $L(\psi^k_n)$ has at least $exp(k,n)$ states is similar to the known proof for $\{ww\Sigma^\omega : |w| = exp(k,n)\}$ and is shown latter.

We then prove a nonelementary lower bound for satisfiability and model-checking of Abort-LTL formulas. We then show that the nonelemetary cost is intrinsic and is not a side-effect of the automata-theoretic approach by proving a nonelementary lower bounds for satisfiability and model checking of Abort-LTL.

We start by considering words of length 2^n; that is, when $k = 1$. Let $\Sigma = \{0,1\}$. For simplicity, we assume that 0 and 1 are disjoint atomic propositions. Each letter of w_1 and w_2 is represented by block of n "cells". The letter itself is stored in the first cell of the block. In addition to the letter, the block stores its position in the word. The position is a number between 0 and $2^n - 1$, referred to as the *value* of the block, and we use an atomic proposition c_1 to encode it as an n-bit vector. For simplicity, we denote $\neg c_1$ by c_0. The vector is stored in the cells of the block, with the least significant bit stored at the first cell. The position is increased by one from one block to the next. The formulas in Γ requires that the first cell of each block is marked with the atomic proposition $\#$, that the first cell in the first block of w_2 is marked with the atomic proposition @, and that the first cell after w_2 is marked by \$. An example of a legal prefix (structure wise) is shown in Figure 1. Formally, Γ contains the following formulas.

																	$
									@								
#		#		#		#		#		#		#		#		#	
0	?	0	?	1	?	1	?	1	?	0	?	1	?	1	?	?	
c_0	c_0	c_0	c_1	c_1	c_0	c_1	c_1	c_0	c_0	c_0	c_1	c_1	c_0	c_1	c_1	?	

Fig. 1. An example for $n = 2$ that represents the case where $w_1 = 0011$ and $w_2 = 1011$. Each row represents a unique atomic proposition, which should hold at exactly the cell in which it is marked. An exception are the propositions 0 and 1 whose values are checked only in the first cell in each block (other cells are marked ?)

- $\gamma_1 = \# \wedge (c_0 \wedge (Xc_0 \wedge \overset{n}{\cdots} \wedge Xc_0)$
  After every $\#$ before the first @ there are $n-1$ cells without $\#$ or @, and then another $\#$.
- $\gamma_2 = (\# \rightarrow \bigwedge_{1 \leq i < n} \mathbf{X}^i(\neg\# \wedge \neg@) \wedge \mathbf{X}^n \#)\, \mathbf{U}\, @$
  The first cell is marked by $\#$ and the first block counter value is $000\ldots0$.

The following four formulas make sure that the position (that is encoded by c_0, c_1) is increased by one every $\#$. We use an additional proposition z that represents the carry. Thus, we add 1 to the least significant bit and then propagate the carry to the other bits. Note that the requirement holds until the last $\#$ before @.

- $\gamma_3 = (((\# \vee z) \wedge c_0) \rightarrow (\mathbf{X}(\neg z) \wedge \mathbf{X}^n\, c_1))\, \mathbf{U}\, (\# \wedge \mathbf{X}((\neg\#)\, \mathbf{U}\, @))$
- $\gamma_4 = ((\neg(\# \vee z) \wedge c_0) \rightarrow (\mathbf{X}(\neg z) \wedge \mathbf{X}^n\, c_0))\, \mathbf{U}\, (\# \wedge \mathbf{X}((\neg\#)\, \mathbf{U}\, @))$
- $\gamma_5 = (((\# \vee z) \wedge c_1) \rightarrow (\mathbf{X}\, z \wedge \mathbf{X}^n\, c_0))\, \mathbf{U}\, (\# \wedge \mathbf{X}((\neg\#)\, \mathbf{U}\, @))$
- $\gamma_6 = ((\neg(\# \vee z) \wedge c_1) \rightarrow (\mathbf{X}(\neg z) \wedge \mathbf{X}^n\, c_1))\, \mathbf{U}\, (\# \wedge \mathbf{X}((\neg\#)\, \mathbf{U}\, @))$

The following formulas require that the first @ is true immediately after w_1.

- $\gamma_7 = ((\# \wedge \bigvee_{0 \leq i < n} X^i c_0) \rightarrow ((\neg@)\, \mathbf{U}\, \mathbf{X}(\# \wedge \neg@)))\, \mathbf{U}\, @$
  as long as the counter is not $111\ldots1$ there not going to be @.
- $\gamma_8 = ((\# \wedge \bigwedge_{0 \leq i < n} X^i c_1) \rightarrow \mathbf{X}^n\, @)\, \mathbf{U}\, @$
  When the counter is $111\ldots1$ the next value going to be @.

The formulas for w_2 are similar, except that they begin with a $\neg@\mathbf{U}(@\wedge\ldots)$, and \$ replaces @. We add the formula $(\neg\$)\, \mathbf{U}\, @$ to make sure that the first \$ is immediately after w_2.

Next, we describe the formula θ, which requires that for all positions $0 \leq j \leq 2^{n-1}$, the j-th letter in w_1 is equal to the j-th position in w_2. While such a universal quantification on j is impossible in LTL, it can be achieved using the abort on operator.

We start with some auxiliary formulas:

$$\theta_= = \# \wedge \bigwedge_{i=0}^{n-1} ((\mathbf{X}^i\, c_0 \wedge ((\neg\$)\, \mathbf{U}\, (\$ \wedge \mathbf{X}^{i+1}\, c_0))) \vee (\mathbf{X}^i\, c_1 \wedge ((\neg\$)\, \mathbf{U}\, (\$ \wedge \mathbf{X}^{i+1}\, c_1))))$$

The formula requires the current position value to agree with the position value right after \$. Then, the formula

$$\theta_{next0} = (\theta_= \wedge ((\neg@)\, \mathbf{U}\, (@ \wedge (((\# \wedge \theta_=) \rightarrow 0)\, \mathbf{U}\, \$)))) \text{ abort on } \$.$$

requires that we are in a beginning of a block in w_1, and every block between @ and \$ whose position is equal to the position of the current block (note that there is exactly one such block) is marked with 0. Intuitively, let

$$\theta'_{next0} = \theta_= \wedge ((\neg@)\, \mathbf{U}\, (@ \wedge (((\# \wedge \theta_=) \rightarrow 0)\, \mathbf{U}\, \$)))$$

Then, θ'_{next0} requires that we are in a beginning of a block in w_1, the block position is equal to the position of the block that starts after \$, and every block between @ and \$

whose position is also equal to the position of the block that starts after \$ is marked with 0. Thus, θ'_{next0} is equivalent to θ_{next0} except that it fails when the current block does not match the block after \$. This is where the abort operator enters the picture. For every position, if the corresponding block is marked 0, the prefix of the word that ends at \$ can be extend such that the current block position match the position of the block that starts after \$. This extension would satisfy θ'_{next0}, thus the word satisfies θ_{next0}. The formula θ_{next1} is defined similarly.

Now, the formula

$$\theta = (((\# \wedge 0) \rightarrow \theta_{next0}) \wedge ((\# \wedge 1) \rightarrow \theta_{next1}\mathbf{U}))@$$

requires that $w_1 = w_2$.

Words of length $exp(k, n)$ So far we have shown how to construct ψ_n^1, which defines equality between words of length $exp(1, n)$. We would like to scale up the technique to construct formulas ψ_n^k that define equality between words of length $exp(k, n)$. (As before, we use @ to mark the end of the first word and we use \$ to mark the end of the second word.) To do that, we encode such words by sequences consisting of $exp(k, n)$ $(k-1)$-blocks, of length $exp(k-1, n)$ each. Each such $(k-1)$-block, whose beginning is marked by $\#_{k-1}$, represents one letter, encoding both the letter itself as well as its position in the word, which requires $exp(k-1, n)$ bits. We need to require that (1) $(k-1)$-blocks behave as an $exp(k-1, n)$-counter, i.e., the first $(k-1)$-block is identically 0, and subsequent $(k-1)$-blocks count modulo $exp(k, n)$, and (2) if there are two $(k-1)$-blocks, b_1 in the first word and b_2 in the second word that encode the same position, then they must encode the same letter. To express (1) and (2), we have to refer to bits inside the $(k-1)$-blocks, which we encode using $(k-2)$-blocks, of length $exp(k-2, n)$.

Thus, we need an inductive construction. We start with 0-blocks, of length n, and use formulas Γ^0 to require that the 0-blocks behave as an n-bit counter (using the formulas $\gamma_1, \ldots, \gamma_8$ from earlier). Inductively, suppose we have already required the $(k-2)$-blocks to behave as an $exp(k-2, n)$ counter. We now want every sequence of $exp(k-1, n)$ $(k-2)$-blocks, initially marked with $\#_{k-1}$, to encode a $(k-1)$ block. We use the values of a proposition c^{k-1} at the start of each $(k-2)$-block to encode the bits of the $(k-1)$-block.

We now need to write formulas analogous to $\gamma_1, \ldots, \gamma_8$ to require that $(k-1)$-block to behave as an $exp(k-1, n)$-bit counter. The difficulty is in referring to bits in the same position of successive $(k-1)$-blocks using formulas of size polynomial in n (for $k = 1$ we can use $\mathbf{X}^n$ to refer to corresponding bits in successive 0-blocks). To refer to corresponding bits in successive $(k-1)$-blocks, we use the fact that each such bit is encoded using $(k-2)$-blocks. Thus, referring to such bits require the comparison of $(k-2)$-blocks. Also, to say that the two words, each of length $exp(k, n)$ are equal we need to express the analog of θ, which requires the analogue of $\theta_=$. But the latter use a conjunction of size n to range over all the n-bits of a 0-block. Here we need to range over all $(k-2)$ blocks and compare pair of such blocks.

Thus, the key is to be able to compare i-blocks, for $i = 0, \ldots, k-1$. Once we are able to compare i-blocks we can go ahead and construct and compare $(i+1)$-blocks. To compare i-blocks for $i \geq 1$ we use the marker $\$_i$. Instead of directly comparing two i-blocks, we compare them both to the i-block that come immediately after $\$_i$, just as in $\theta_=$ we compared two 0-blocks to the 0-block that comes immediately after the \$ marker. By "aborting on" $\$_i$ we make sure that we are comparing the two i-blocks to *some* i-block that could come after $\$_i$; this way we are not bound to some specific i-block that actually comes after $\$_i$.

ψ_n^k is a conjunction of a sequence of sets of formulas. The construction of the sets of formulas is inductive, for every level i ($0 \leq i \leq k$), we define Γ^i and Θ^i that require level i to be "legal" and make some "tools" for level $i+1$. The set Γ^i requires the followings:

– γ_1^i requires that the counter value of the first i-block is $000\ldots0$.
– γ_2^i requires that after every $\#_i$ before the next $\#_i$ there are $exp(i,n)$ many $(i-1)$-blocks without $\#_i$. This formula is only needed in level 0, after that it is taken care of by γ_7^{i-1} and γ_8^{i-1}.
– The following four formulas (γ_3^i, γ_4^i, γ_5^i, and γ_6^i) make sure that the counter (that is encoded by c_0^i, c_1^i) value is increased by one every $\#_i$. We use an additional proposition z^i that represents the carry.
– In the following two formulas (γ_7^i and γ_8^i), the first $k-1$ levels are a bit different from the kth level. The first $k-1$ levels require that at the $\#_{i+1}$ proposition will be true only at the beginning of every $(i+1)$-block. The formulas of the kth level require that the @ will be true exactly at the beginning of w_2.

A similar set of formulas is used for w_2. In addition for $i>0$, we require that the first $\$_i$ marker appears after w_1 and w_2, and that the first $\$_i$ is proceeded by a legal i-block, and that i-block is proceeded by the first $\$_{i-1}$. These requirements can be formulated easily using formulas similar of formulas of Γ^i.

The Θ^i set requires two basic conditions:

1. A formula $\theta^i_{\#next0}$ that requires that the i-block between the next $\#_{(i+1)}$ and the one after, which has the same position value as the current i-block, represents the letter c_0^{i+1}. (A similar formula is needed for c_1^{i+1}).
2. A formula $\theta^i_{\$next0}$ that requires that the i-block in the $(i+1)$-block that starts after the first $\$_{(i+1)}$, and has the same position value as the current i-block, represents the letter c_0^{i+1}. (A similar formula is needed for c_1^{i+1}).

both formulas uses the auxiliary formula $\theta^i_=$ that requires the current i-block to be equivalent to the i-block that starts right after the first $\$_i$.

The base of the inductive construction is Γ^0, Θ^0, which are similar to the formulas that presented in the former section:

– $\gamma_1^0 = \#_0 \wedge \bigwedge_{0\le i<n} \mathbf{X}^i\, c_0^0$
– $\gamma_2^0 = (\#_0 \rightarrow (\bigwedge_{1\le i<n} \mathbf{X}^i(\neg\#_0) \wedge \mathbf{X}^n\, \#_0))\, \mathbf{U}\, @$
– $\gamma_3^0 = (((\#_0 \vee z_0) \wedge c_0^0) \rightarrow (\mathbf{X}(\neg z_0) \wedge \mathbf{X}^n\, c_1^0))\, \mathbf{U}\, (\#_0 \wedge \mathbf{X}(\neg\#_0)\, \mathbf{U}\, @)$
– $\gamma_4^0 = ((\neg(\#_\vee z_0) \wedge c_0^0) \rightarrow (\mathbf{X}(\neg z_0) \wedge \mathbf{X}^n\, c_0^0))\, \mathbf{U}\, (\#_0 \wedge \mathbf{X}(\neg\#_0)\, \mathbf{U}\, @)$
– $\gamma_5^0(((\#_0 \vee z_0) \wedge c_1^0) \rightarrow (\mathbf{X}\, z_0 \wedge \mathbf{X}^n\, c_0^0))\, \mathbf{U}\, (\#_0 \wedge \mathbf{X}(\neg\#_0)\, \mathbf{U}\, @)$
– $\gamma_6^0((\neg(\#_0 \vee z_0) \wedge c_1^0) \rightarrow (\mathbf{X}(\neg z_0) \wedge \mathbf{X}^n\, c_1^0))\, \mathbf{U}\, (\#_0 \wedge \mathbf{X}(\neg\#_0)\, \mathbf{U}\, @)$

The following formulas require that the $\#_1$ proposition is true exactly at the beginning of every 1-block.

– $\gamma_7^0 = ((\#_0 \wedge \bigvee_{0\le i<n} X^i c_0^0) \rightarrow ((\neg\#_1)\, \mathbf{U}\, (\mathbf{X}(\#_0 \wedge \neg\#_1)))\, \mathbf{U}\, @$
– $\gamma_8^0((\#_0 \wedge \bigwedge_{0\le i<n} X^i c_1^0) \rightarrow \mathbf{X}^n\, \#_1)\, \mathbf{U}\, @$

Next we define Θ^0. We start with the auxiliary formula
$\theta^0_= = \bigwedge_{i=0}^{n-1}((\mathbf{X}^i\, c_0^0 \wedge ((\neg\$_0)\, \mathbf{U}\, (\$_0 \wedge \mathbf{X}^{i+1}\, c_0^0))) \vee (\mathbf{X}^i\, c_1^0 \wedge ((\neg\$_0)\, \mathbf{U}\, (\$_0 \wedge \mathbf{X}^{i+1}\, c_1^0))))$
that requires that the current 0-block position is equal to the position value of the 0-block that starts after the first $\$_0$. The formulas of Θ^0 are:

1. $\theta^0_{\#next0} = (\theta^0_= \wedge \mathbf{X}((\neg\#_1)\, \mathbf{U}\, (\#_1 \wedge (((\#_0 \wedge \theta^0_=) \rightarrow c_0^1)\, \mathbf{U}\, \mathbf{X}\, \#_1))))$ abort on $\$_0$ requires that the matching 0-block in the next 1-block represents c_0^1.
2. $\theta^0_{\$next0} = (\theta^0_= \wedge \mathbf{X}((\neg\$_1)\, \mathbf{U}\, (\$_1 \wedge \mathbf{X}(((\#_0 \wedge \theta^0_=) \rightarrow c_0^1)\, \mathbf{U}\, \mathbf{X}\, \$_0))))$ abort on $\$_0$ requires that in the 1-block that starts after $\$_1$ and proceeded by $\$_0$, the matching 0-block represents c_0^1.
3. $\theta^0_{\#next1}$ and $\theta^0_{\$next1}$ are defined similarly.

Assume that for some $1 < i \le k$, we already construct Γ^j and Θ^j for every $j < i$. We show how to construct Γ^i and Θ^i. First we describe Γ^i:

– $\gamma_1^i = (\#_{i-1} \rightarrow c_0^i)\,\mathbf{U}\,\mathbf{X}\,\#_i$.

The following four formulas require that the positions of the i-blocks increase by one form one block to the next. We use the $\theta^{i-1}_{\#next0}$ and $\theta^{i-1}_{\#next1}$ formulas instead of the $\mathbf{X}^n$ operator.

– $\gamma_3^i = ((\#_{i-1} \wedge (\#_i \vee z^i) \wedge c_0^i) \rightarrow (\mathbf{X}((\neg\#_{i-1})\,\mathbf{U}\,(\#_{i-1} \wedge (\neg z^i))) \wedge \theta^{i-1}_{\#next1}))\,\mathbf{U}\,(\#_i \wedge \mathbf{X}(\neg\#_i)\,\mathbf{U}\,@)$
– $\gamma_4^i = ((\#_{i-1} \wedge \neg(\#_i \vee z^i) \wedge c_0^i) \rightarrow (\mathbf{X}((\neg\#_{i-1})\,\mathbf{U}\,(\#_{i-1} \wedge (\neg z^i))) \wedge \theta^{i-1}_{\#next0}))\,\mathbf{U}\,(\#_i \wedge \mathbf{X}(\neg\#_i)\,\mathbf{U}\,@)$
– $\gamma_5^i(((\#_{i-1} \wedge \#_i \vee z^i) \wedge c_1^i) \rightarrow (\mathbf{X}((\neg\#_{i-1})\,\mathbf{U}\,(\#_{i-1} \wedge (z^i))) \wedge \theta^{i-1}_{\#next0}))\,\mathbf{U}\,(\#_i \wedge \mathbf{X}(\neg\#_i)\,\mathbf{U}\,@)$
– $\gamma_6^i((\#_{i-1} \wedge \neg(\#_{i-1} \vee z^i) \wedge c_1^i) \rightarrow (\mathbf{X}((\neg\#_{i-1})\,\mathbf{U}\,(\#_{i-1} \wedge (\neg z^i)))) \wedge \theta^{i-1}_{\#next1})\,\mathbf{U}\,(\#_i \wedge \mathbf{X}(\neg\#_i)\,\mathbf{U}\,@)$

The following two formulas require that the $\#_{i+1}$ proposition will be true only at the beginning of every $(i+1)$-block. The formulas of the kth level that require that the first @ is true exactly at the beginning of w_2 are very similar, thus, omitted.

– $\gamma_7^i = ((\#_i \wedge (\neg((\#_{i-1} \rightarrow c_1^i)\,\mathbf{U}\,\mathbf{X}\,\#_i))) \rightarrow \mathbf{X}((\neg\#_i)\,\mathbf{U}\,(\mathbf{X}(\#_i \wedge \neg\#_{i+1})))\,\mathbf{U}\,@$ - as long as the i-block is not $111\ldots1$ there not going to be $\#_{i+1}$.
– $\gamma_8^i = ((\#_i \wedge ((\#_{i-1} \rightarrow c_1^i)\,\mathbf{U}\,\mathbf{X}\,\#_i)) \rightarrow \mathbf{X}((\neg\#_i)\,\mathbf{U}\,(\mathbf{X}(\#_i \wedge \#_{i+1})))\,\mathbf{U}\,@$ - When the i-block is $111\ldots1$ the next value going to be $\#_{i+1}$.

Next, we define Θ^i, we start with the auxiliary formula
$\theta^i_= = (((\#_{i-1} \wedge c_0^i) \rightarrow \theta^{i-1}_{\$next0}) \wedge ((\#_{i-1} \wedge c_1^i) \rightarrow (\theta^{i-1}_{\$next1})))\,\mathbf{U}\,\mathbf{X}\,\#_i$
that requires that the current i-block position value is equal to the i-block that starts after $\$_i$. The formulas of Θ^i are:

1. $\theta^i_{\#next0} = (\theta^i_= \wedge ((\neg\#_{i+1})\,\mathbf{U}\,(\#_{i+1} \wedge (((\#_i \wedge \theta^i_=) \rightarrow c_0^i)\,\mathbf{U}\,\mathbf{X}\,\#_{i+1}))))$ abort on $\$_i$ requires that the matching i-block in the next $(i+1)$-block represents c_0^{i+1}.
2. $\theta^i_{\$next0} = (\theta^i_= \wedge ((\neg\$_{i+1})\,\mathbf{U}\,(\$_{i+1} \wedge \mathbf{X}(((\#_i \wedge \theta^i_=) \rightarrow c_0^{i+1})\,\mathbf{U}\,\mathbf{X}\,\#_{i+1}))))$ abort on $\$_i$ requires that the matching i-block in the $(i+1)$-block that starts after $\$_{i+1}$ represents c_0^{i+1}.
3. $\theta^i_{\#next1}$ and $\theta^i_{\$next1}$ are defined similarly.

Note that $\theta^{k-1}_{\$next0}$ uses a k nesting depth of the abort on operator.

The last formula that we define requires w_1 and w_2 to be equivalent. First we define
$\theta^i_{@next0} = (\theta^{k-1}_= \wedge (\neg@)\,\mathbf{U}\,@ \wedge \mathbf{X}(((\#_{k-1} \wedge \theta^k_=) \rightarrow 0)\,\mathbf{U}\,\mathbf{X}\,@))$ abort on $\$_{k-1}$
that requires that the matching $(k-1)$-block in w_2 represents 0. Next, we define $\theta^i_{@next1}$ in a similar way. Then, we define
$\theta_{=w} = (((\#_{k-1} \wedge 0) \rightarrow \theta^{k-1}_{@next0}) \wedge ((\#_{k-1} \wedge 1) \rightarrow (\theta^{k-1}_{@next1})))\,\mathbf{U}\,\mathbf{X}\,@$
that requires that $w_1 = w_2$

We now discuss the length of the formulas in the above reduction. For every $0 \leq i \leq k$, we have a constant number of formulas in Γ^i and Θ^i, thus the number of formulas is $O(k)$. The length of some of the formulas of level 0 is $O(n^2)$ because we use sub-formulas of the form $\bigwedge_{0 \leq i < n} \mathbf{X}^i$ (using nesting, we can write equivalent formulas of size $O(n)$).

In Levels 2 to k, we have formulas γ_1^i, γ_7^i, and γ_8^i of constance length. The problem is in formulas γ_3^i, γ_4^i, γ_5^i, and γ_6^i, where we use the sub-formula $\theta^{i-1}_{\#next0}$ or $\theta^{i-1}_{\#next1}$, which recursively depend on formulas of lower levels. We can overcome this problem by using auxiliary propositions. The real problem is the length of the formulas of Θ^i because there, these sub-formulas are defined recursively and cannot be replaced by auxiliary propositions. Since the formula $\theta^i_=$ contains four sub-formulas $\theta^{i-1}_=$, the length of $\theta^k_=$ is $O(4^k)$. Thus the total length of the formulas is $O(4^k+n)$. Note that the length of w is $\Omega(exp(k,n))$ where k is the nesting depth of the abort on operator, and n is the length of the formula.

Lemma 1. *Every ABW that accept ψ_n^k has at least $exp(k,n)$ states.*

The proof of Lemma 1 appear in Appendix B. Lemma 1 shows that the the automata-theoretic approach to Abort-LTL has a nonelementary cost. We now show that this cost is intrinsic to Abort-LTL and is not an artifact of the automata-theoretic approach.

Satisfiability and model-checking for Abort-LTL We now prove that satisfiability checking for Abort-LTL is SPACE($exp(k,n)$)-hard. We show a reduction from a hyper-exponent version of the *tiling problem* [23, 10, 17]. The problem is defined as follows relative to a parameter $k > 0$. We are given a finite set T, two relations $V \subseteq T \times T$ and $H \subseteq T \times T$, an initial tile t_0, a final tile t_a,and a bound $n > 0$. We have to decide whether there is some $m > 0$ and an a tiling of an $exp(k,n) \times m$-grid: such that: (1) t_0 is in the bottom left corner and t_a is in the top left corner, (2) Every pair of horizontal neighbors is in H, and (3) Every pair of vertical neighbors is in V. Formally: Is there a function $f : (exp(k,n) \times m) \to T$ such that (1) $f(0,0) = t_0$ and $t(0,m-1) = t_a$, (2) for every $0 \leq i < exp(k,n)$, and $0 \leq j < m$, we have that $(f(i,j), f(i+1,j)) \in H$, and (3) for every $0 \leq i < exp(k,n)$, and $0 \leq j < m-1$, we have that $(f(j,i), f(j,i+1)) \in V$. This problem is known to be SPACE($exp(k,n)$)-complete [10, 17].

We reduce this problem to the satisfiability problem for $\mathsf{Abort-LTL}$. Given a tiling problem $\tau = \langle T, H, V.t_0, t_f, n\rangle$, we construct a formula ψ_τ such that τ admits tiling iff ψ_τ is satisfiable. The idea is to encode a tiling as a word over T, consisting of a sequence of blocks of length $l = exp(k,n)$, each encoding one row of the tiling. Such a word represents a proper tiling if it starts with t_0, ends with a block that starts with t_a, every pair of adjacent tiles in a row are in H, and every pair of tiles that are $exp(k,n)$ tiles apart are in V. The difficulty is in relating tiles that are far apart. To do that we represent every tile by a $(k-1)$-block, of length $exp(k-1,n)$, which represent the tiles position in the row. As we had earlier, to require that the $(k-1)$-blocks behave as a $exp(k-1,n)$-bit counter and to compare $(k-1)$-blocks, we need to construct them from $(k-2)$-blocks, which needs to be constructed from $(k-3)$-blocks, and so on. Thus, as we had earlier, we need an inductive construction of i-blocks, for $i = 1, \ldots, k-1$, and we need to adapt the machinery of the previous nonelementary lower-bound proof.

In Appendix B.2, we show an exponential reduction from the nonelementary domino problem to the satisfiability of Abort-LTL formulas. Thus the satisfiability problem of the Abort-LTL is non-elementary hard.

Theorem 6. *The satisfiability and model-checking problems for* Abort-LTL *formulas nesting depth k of* abort on *are SPACE($exp(k,n)$)-complete.*

5 Concluding Remarks

We showed in this paper that the distinction between reset semantics and abort semantics has a dramatic impact on the complexity of using the language in a model-checking tool. While Reset-LTL enjoys the "fast-compilation property"–there is a linear translation of Reset-LTL formulas into alternating Büchi automata, the translation of Abort-LTL formulas into alternating Büchi automata is nonelementary, as is the complexity of satisfiability and model checking for Abort-LTL. This raises a concern on the feasibility of implementing a model checker for logics based on Abort-LTL(such as Sugar 2.0). While the nonelementary blow-up is a worst-case prediction, one can conclude from our results that while Reset-LTL can be efficiently compiled using a rather modest extension to existing LTL compilers (e.g., [4, 3]), a much more sophisticated automata-theoretic machinery is needed to implement an optimizing compiler for Abort-LTL–an issued that is not addressed in the documentation of Sugar 2.0.

A Proofs for section 3

A.1 Upper bound

The following lemma implies Theorem 2.

Lemma 2. *Let ψ be a* Reset-LTL *formula and let φ be a subformula of ψ. Then, $\mathcal{A}_{\psi,\varphi}$ accepts an infinite word w iff $\langle w, acc_\psi[\varphi], rej_\psi[\varphi]\rangle \models \varphi$.*

Proof. The proof is by induction over the structure of ψ. Let $a' = acc_\psi[\varphi]$ and $r' = rej_\psi[\varphi]$.

- For the base case, let φ be an atomic proposition p. By the definition of δ, $\mathcal{A}_{\psi,\psi}$ accepts w iff $w_0 \models (a' \vee (p \wedge \neg r'))$. By the semantics of Reset-LTL, this holds iff $\langle w, a', r'\rangle \models \varphi$.
- We prove the closure of the induction over the operators of Reset-LTL. We assume that for the subformulas ψ_1 and ψ_2 of ψ, the lemma holds. Let $a_1 = acc_\psi[\psi_1]$, $r_1 = rej_\psi[\psi_1]$, $a_2 = acc_\psi[\psi_2]$, $r_2 = rej_\psi[\psi_2]$.
  - For $\varphi = \neg\psi_1$ we have $a_1 = r'$ and $r_1 = a'$. Then, by the definition of the AWW, $\mathcal{A}_{\psi,\varphi}$ accepts w iff $\mathcal{A}_{\psi,\psi_1}$ does not accept w. By the induction hypothesis, this holds iff $\langle w, a_1, r_1\rangle \not\models \psi_1$. The semantics of Reset-LTL implies that this holds iff $\langle w, a', r'\rangle \models \varphi$
  - For $\varphi = \psi_1 \wedge \psi_2$ we have $a_1 = a_2 = a'$ and $r_1 = r_2 = r'$. Then, by the definition of the AWW, $\mathcal{A}_{\psi,\varphi}$ accepts w iff $\mathcal{A}_{\psi,\psi_1}$ accepts w and $\mathcal{A}_{\psi,\psi_2}$ accepts w. By the induction hypothesis, this holds iff $\langle w, a_1, r_1\rangle \models \psi_1$ and $\langle w, a_2, r_2\rangle \models \psi_2$. The semantics of Reset-LTL implies that this holds iff $\langle w, a', r'\rangle \models \varphi$
  - The proof for $\varphi = \psi_1 \vee \psi_2$ is similar.
  - For $\varphi = \mathbf{X}\,\psi_1$ we have $a_1 = a'$ and $r_1 = r'$. Then, by the definition of the AWW, $\mathcal{A}_{\psi,\varphi}$ accepts w iff $w_0 \models a'$ or ($\mathcal{A}_{\psi,\psi_1}$ accepts w^1 and $w_0 \not\models r'$). By the induction hypothesis, this holds iff $w_0 \models a'$ or ($\langle w^1, a_1, r_1\rangle \models \psi_1$ and $w_0 \not\models r'$). The semantics of Reset-LTL implies that this holds iff $\langle w, a', r'\rangle \models \varphi$
  - For $\varphi = \psi_1\ \mathbf{U}\ \psi_2$ we have $a_1 = a_2 = a'$ and $r_1 = r_2 = r'$. Then, by the definition of the AWW, $\mathcal{A}_{\psi,\varphi}$ accepts w iff $\mathcal{A}_{\psi,\psi_2}$ accepts w or ($\mathcal{A}_{\psi,\psi_1}$ accepts w and $\mathcal{A}_{\psi,\varphi}$ accepts w^1). By the induction hypothesis, this holds iff $\langle w, a', r'\rangle \models \psi_2$ or ($\langle w, a_1, r_1\rangle \models \psi_1$ and $\mathcal{A}_{\psi,\varphi}$ accepts w^1) in this case the same should hold for w^1. Note that the initial state of $\mathcal{A}_{\psi,\varphi}$ is not in F_φ thus every accepting run of $\mathcal{A}_{\psi,\varphi}$ exit this state after k steps for some finite k. For this k the following holds: $\langle w^k, a', r'\rangle \models \psi_2$ and for every $j < k$, we have $\langle w^j, a_1, r_1\rangle \models \psi_1$. The semantics of Reset-LTL implies that this holds iff $\langle w, a', r'\rangle \models \varphi$
  - For $\varphi =$ accept b in ψ_1 we have $a_1 = a' \vee (b \wedge \neg r')$ and $r_1 = r'$. Since $\mathcal{A}_{\psi,\varphi} = \mathcal{A}_{\psi,\psi_1}$, the induction hypothesis implies that $\mathcal{A}_{\psi,\varphi}$ accept w iff $\langle w, a_1, r_1\rangle \models \psi_1$. The semantics of Reset-LTL implies that this holds iff $\langle w, a', r'\rangle \models \varphi$
  - For $\varphi =$ reject b in ψ_1 we have $a_1 = a'$ and $r_1 = r' \vee (b \wedge \neg a')$. Since $\mathcal{A}_{\psi,\varphi} = \mathcal{A}_{\psi,\psi_1}$, the induction hypothesis implies that $\mathcal{A}_{\psi,\varphi}$ accept w iff $\langle w, a_1, r_1\rangle \models \psi_1$. The semantics of Reset-LTL implies that this holds iff $\langle w, a', r'\rangle \models \varphi$

Translating Reset-LTL into LTL Given an Reset-LTL formula ψ we define a transformation $\mathcal{T}$ that transform ψ into an LTL formula $\mathcal{T}(\psi)$, such that for every infinite word w, $\langle w, \mathbf{False}, \mathbf{False}\rangle \models \psi \Leftrightarrow w \models \mathcal{T}(\psi)$. $\mathcal{T}$ is defined inductively on the subformulas of ψ as follows:

Definition 2. *Let φ be a subformula of ψ, then:*

- *If $\varphi = p$ (atomic proposition), then, $\mathcal{T}(\varphi) = acc_\psi[\varphi] \vee (\varphi \wedge \neg rej_\psi[\varphi])$.*
- *If $\varphi = \neg\psi_1$ then $\mathcal{T}(\varphi) = \neg\mathcal{T}(\psi_1)$.*
- *If $\varphi = \psi_1 \wedge \psi_2$ then $\mathcal{T}(\varphi) = \mathcal{T}(\psi_1) \wedge \mathcal{T}(\psi_2)$.*

– *If* $\varphi = \psi_1 \vee \psi_2$ *then* $\mathcal{T}(\varphi) = \mathcal{T}(\psi_1) \vee \mathcal{T}(\psi_2)$.
– *If* $\varphi = \mathbf{X}\,\psi_1$ *then,* $\mathcal{T}(\varphi) = acc_\psi[\varphi] \vee (\mathcal{T}(\psi_1) \wedge \neg rej_\psi[\varphi])$.
– *If* $\varphi = \psi_1\,\mathbf{U}\,\psi_2$ *then* $\mathcal{T}(\varphi) = (\neg rej_\psi[\varphi] \wedge \mathcal{T}(\psi_1))\,\mathbf{U}\,(acc_\psi[\varphi] \vee (\mathcal{T}(\psi_2) \wedge \neg rej_\psi[\varphi]))$[6]
– *If* $\varphi =$ accept b in ψ_1 *then* $\mathcal{T}(\varphi) = \mathcal{T}(\psi_1)$.
– *If* $\varphi =$ reject b in ψ_1 *then* $\mathcal{T}(\varphi) = \mathcal{T}(\psi_1)$.

For example consider the formula

$$\psi = (\text{accept } p_0 \text{ in } \mathbf{X}\,p_1) \vee (\text{reject } \neg p_3 \text{ in } (p_1\,\mathbf{U}\,(p_4 \wedge p_5)))$$

The subformulas of ψ are: $\psi_1 = p_1$, $\psi_2 = \mathbf{X}\,\psi_1$, $\psi_3 =$ accept p_0 in ψ_2, $\psi_4 = p_1$, $\psi_5 = p_4$, $\psi_6 = p_5$, $\psi_7 = \psi_5 \wedge \psi_6$, $\psi_8 = \psi_4\,\mathbf{U}\,\psi_7$, $\psi_9 =$ reject $\neg p_2$ in ψ_8, and $\psi = \psi_3 \vee \psi_9$.

First, we compute the acc and rej Boolean formulas for every subformula of ψ:
$acc_\psi[\psi_3] = rej_\psi[\psi_3] = acc_\psi[\psi_9] = rej_\psi[\psi_9] = rej_\psi[\psi_1] = rej_\psi[\psi_2] = acc_\psi[\psi_4] = acc_\psi[\psi_5] = acc_\psi[\psi_6] = acc_\psi[\psi_7] = acc_\psi[\psi_8] = \mathbf{False}$,
$acc_\psi[\psi_1] = acc_\psi[\psi_2] = p_0$, and
$rej_\psi[\psi_4] = rej_\psi[\psi_5] = rej_\psi[\psi_6] = rej_\psi[\psi_7] = rej_\psi[\psi_8] = \neg p_3$.

Next, we inductively compute $\mathcal{T}(\psi)$:

$$\mathcal{T}(\psi_1) = p_0 \vee (p_1 \wedge \neg\mathbf{False})$$

$$\mathcal{T}(\psi_2) = p_0 \vee (\mathbf{X}\,\mathcal{T}(\psi_1) \wedge \neg\mathbf{False})$$

$$\mathcal{T}(\psi_3) = \mathcal{T}(\psi_2)$$

$$\mathcal{T}(\psi_4) = \mathbf{False} \vee (p_1 \wedge \neg\neg p_3)$$

$$\mathcal{T}(\psi_5) = \mathbf{False} \vee (p_4 \wedge \neg\neg p_3)$$

$$\mathcal{T}(\psi_6) = \mathbf{False} \vee (p_5 \wedge \neg\neg p_3)$$

$$\mathcal{T}(\psi_7) = \mathcal{T}(\psi_5) \wedge \mathcal{T}(\psi_6)$$

$$\mathcal{T}(\psi_8) = (\neg\neg p_3 \wedge \mathcal{T}(\psi_4))\,\mathbf{U}\,(\mathbf{False} \vee (\mathcal{T}(\psi_7) \wedge \neg\neg p_3))$$

$$\mathcal{T}(\psi_9) = \mathcal{T}(\psi_8)$$

$$\mathcal{T}(\psi) = \mathcal{T}(\psi_3) \vee \mathcal{T}(\psi_9)$$

After taking out the **False** and $\neg\neg$ operations we get:

$$\mathcal{T}(\psi) = (p_0 \vee \mathbf{X}(p_0 \vee p_1)) \vee$$

$$((p_3 \wedge (p_1 \wedge p_3))\,\mathbf{U}\,(((p_4 \wedge p_3) \wedge (p_5 \wedge p_3)) \wedge p_3))$$

Theorem 7. *Let* ψ *be a* Reset-LTL *formula and let* φ *be a subformula of* ψ *. Then* $\langle w, acc_\psi[\varphi], rej_\psi[\varphi]\rangle \models \varphi$ *if and only if* $w \models \mathcal{T}(\varphi)$.

[6] The subformulas acc and rej are monotonic, i.e., if ψ_1 is a subformula of φ then $acc_\psi[\varphi] \rightarrow acc_\psi[\psi_1]$ and $rej_\psi[\varphi] \rightarrow rej_\psi[\psi_1]$. Using this fact, one can prove that $\mathcal{T}(\psi_1\,\mathbf{U}\,\psi_2) = \mathcal{T}(\psi_1)\,\mathbf{U}\,\mathcal{T}(\psi_2)$ is a sufficient definition. For simplicity use a more intuitive definition.

Proof. : We prove the theorem by induction of the structure of the subformulas: Let $a' = acc_\psi[\varphi], r' = rej_\psi[\varphi]$

- For the base case: $\psi = p$. $\langle w, acc_\psi[p], rej_\psi[p]\rangle \models p$ iff $w_0 \models acc_\psi[p] \vee (p \wedge \neg rej_\psi[p])$ iff $w \models \mathcal{T}(\varphi)$.
- For the closure of the induction assume that for the subformulas ψ_1 and ψ_2 of φ for which $a_1 = acc_\psi[psi_1]$, $r_1 = rej_\psi[\psi_1]$, $a_2 = acc_\psi[\psi_2]$, and $r_2 = rej_\psi[\psi_2]$, the following holds: $\langle w, a_1, r_1\rangle \models \psi_1$ if and only if $w \models \mathcal{T}(\psi_1)$ and $\langle w, a_2, r_2\rangle \models \psi_2$ if and only if $w \models \mathcal{T}(\psi_2)$. We prove that the theorem holds for φ.
  - If $\varphi = \neg\psi_1$, then by the semantics of Reset-LTL, $\langle w, a', r'\rangle \models \varphi$ iff $\langle w, r', a'\rangle \not\models \psi_1$. By Definition 1 $a_1 = r'$ and $r_1 = a'$. The induction hypothesis implies that $\langle w, a_1, r_1\rangle \not\models \psi_1$ iff $w \not\models \mathcal{T}(\psi_1)$. By Definition 2, $w \not\models \mathcal{T}(\psi_1)$ iff $w \models \mathcal{T}(\varphi)$.
  - If $\varphi = \psi_1 \wedge \psi_2$ then by Definition 1, $a' = a_1 = a_2$ and $r' = r_1 = r_2$. By the semantic of Reset-LTL, $\langle w, a', r'\rangle \models \varphi$ iff $\langle w, a_1, r_1\rangle \models \psi_1$ and $\langle w, a_2, r_2\rangle \models \psi_2$. The induction hypothesis implies that $\langle w, a_1, r_1\rangle \models \psi_1$ and $\langle w, a_2, r_2\rangle \models \psi_2$ iff $w \models \mathcal{T}(\psi_1)$ and $w \models \mathcal{T}(\psi_2)$. By Definition 2, $w \models \mathcal{T}(\psi_1)$ and $w \models \mathcal{T}(\psi_2)$ iff $w \models \mathcal{T}(\varphi)$.
  - If $\varphi = \psi_1 \vee \psi_2$ then by Definition 1, $a' = a_1 = a_2$ and $r' = r_1 = r_2$. By the semantic of Reset-LTL, $\langle w, a', r'\rangle \models \varphi$ iff $\langle w, a_1, r_1\rangle \models \psi_1$ or $\langle w, a_2, r_2\rangle \models \psi_2$. The induction hypothesis implies that $\langle w, a_1, r_1\rangle \models \psi_1$ or $\langle w, a_2, r_2\rangle \models \psi_2$ iff $w \models \mathcal{T}(\psi_1)$ or $w \models \mathcal{T}(\psi_2)$. By Definition 2, $w \models \mathcal{T}(\psi_1)$ or $w \models \mathcal{T}(\psi_2)$ iff $w \models \mathcal{T}(\varphi)$.
  - If $\varphi = \mathbf{X}\,\psi_1$ then by Definition 1, $a_1 = a'$ and $r_1 = r'$. By the semantics of Reset-LTL, $\langle w, a', r'\rangle \models \varphi$ iff $w_0 \models a' \vee (\langle w^1, a', r'\rangle \models \psi_1 \wedge w_0 \not\models r')$. The induction hypothesis implies that $\langle w^1, a_1, r_1\rangle \models \psi_1$ iff $w^1 \models \mathcal{T}(\psi_1)$. By Definition 2, $w_0 \models a' \vee (w^1 \models \mathcal{T}(\psi_1) \wedge w_0 \not\models r')$ iff $w \models \mathcal{T}(\varphi)$.
  - If $\varphi = \psi_1\ \mathbf{U}\ \psi_2$ then by Definition 1, $a' = a_1 = a_2$ and $r' = r_1 = r_2$. By the semantics of Reset-LTL, $\langle w, a', r'\rangle \models \varphi$ iff there exists k such that ($w_k \models a'$ or ($\langle w^k, a', r'\rangle \models \psi_2$ and $w_k \not\models r'$)) and for every $j < k$, ($\langle w^j, a', r'\rangle \models \psi_1$ and $w_j \not\models r'$). The induction hypothesis implies that this holds iff there exists k such that ($w_k \models a'$ or ($w^k \models \mathcal{T}(\psi_2)$ and $w_k \not\models r'$)) and for every $j < k$, ($w^j \models \mathcal{T}(\psi_1)$ and $w_j \not\models r'$). By Definition 2,this holds iff $w \models \mathcal{T}(\varphi)$.
  - If $\varphi =$ accept b in ψ_1 then, by Definition 1, $a_1 = a' \vee (b \wedge \neg r')$ and $r_1 = r'$. By the semantics of Reset-LTL, $\langle w, a', r'\rangle \models \varphi$ iff $\langle w, a' \vee (b \wedge \neg r'), r'\rangle \models \psi_1$. The induction hypothesis implies that this holds iff $w \models \mathcal{T}(\psi_1)$. By Definition 2,this holds iff $w \models \mathcal{T}(\varphi)$.
  - If $\varphi =$ reject b in ψ_1 then, by Definition 1, $a_1 = a'$ and $r_1 = r' \vee (b \wedge \neg a')$. By the semantics of Reset-LTL, $\langle w, a', r'\rangle \models \varphi$ iff $\langle w, a', r' \vee (b \wedge \neg a')\rangle\ models \psi_1$. The induction hypothesis implies that this holds iff $w \models \mathcal{T}(\psi_1)$. By Definition 2,this holds iff $w \models \mathcal{T}(\varphi)$.

□

Theorem 7 implies Corollary 1.

Corollary 1. *Let ψ be an* Reset-LTL *formula. Then, for every trace w, we have that w satisfies ψ iff w satisfies $\mathcal{T}(\psi)$.*

Corollary 1 implies that the Reset-LTL is expressively equivalent to LTL.
The size of the translation depends on the representation. The size of the LTL formula $\mathcal{T}(\psi)$ is at most quadratic in the number of subformulas in ψ (assuming linear representation for the $acc_\psi[], rej_\psi[]$ Boolean formulas). Thus if every subformula of ψ has a unique representation, (tree representation) then the size of the automaton is quadratic in the representation of the formula. However, if subformulas that are syntactically equivalent are unified (DAG representation), then one vertex in the DAG that represents a Reset-LTL subformula, could be related to many different subformulas in $\mathcal{T}(\psi)$, which differ in their context. Since every DAG with depth n can be unrolled to a tree of size 2^n, the number of subformulas in $\mathcal{T}(\psi)$ is bounded by $2^{|\psi|}$.

A.2 Lower bound for satisfiability of Reset-LTL when represented as a DAG

In Section 3 we describe algorithms for satisfiability and model-checking of Reset-LTL formulas. We show different results for different representation of the Reset-LTL formulas. When the formula are represented as a tree, the time complexity for satisfiability and model-checking is exponential. Since Reset-LTL contains the LTL logic, and these problems are PSPACE hard for LTL, we do not expect a better upper bound.

However, when we use DAG representation, the time complexity is doubly-exponential. In this section we show that the satisfiability problem of the Reset-LTL logic is **EXPSPACE**, where the formulas are represented as a DAG. Thus, again we do not expect a better upper bound.

For the lower bound, We show a reduction from a EXPSPACE version of the *tiling problem* [23, 10, 17]. The problem is defined as follows. We are given a finite set T, two relations $V \subseteq T \times T$ and $H \subseteq T \times T$, an initial tile t_0, a final tile t_a,and a bound $n > 0$. We have to decide whether there is some $m > 0$ and an a tiling of an $exp(2, n) \times m$-grid: such that: (1) t_0 is in the bottom left corner and t_a is in the top left corner, (2) Every pair of horizontal neighbors is in H, and (3) Every pair of vertical neighbors is in V. Formally: Is there a function $f : (exp(2, n) \times m) \to T$ such that (1) $f(0, 0) = t_0$ and $t(0, m - 1) = t_a$, (2) for every $0 \leq i < exp(2, n)$, and $0 \leq j < m$, we have that $(f(i, j), f(i + 1, j)) \in H$, and (3) for every $0 \leq i < exp(k, n)$, and $0 \leq j < m - 1$, we have that $(f(j, i), f(j, i + 1)) \in V$. This problem is known to be SPACE($exp(k, n)$)-complete [10, 17].

Given a domino problem $\langle T, V, H, \tau_0, \tau_a, n\rangle$ we define a formula ψ with size linear in n such that ψ is satisfiable iff there exists a legal tiling. The formula refer to an infinite word w where some finite prefix w' represents the tiling. Every $l = exp(2, n)$ letters in the prefix represents one row in the grid. Where, every letter in the word is represented by a block of n states. In addition to representing the letter, each block represents the position of the letter in its row. Thus, each block represents a counter that increase from one block to the next modulo l. The counter value is binary encoded by a single proposition, for convenience we refer to this proposition value as c_0 and c_1. The first state of each block is marked by $\#$. A block represents the letter that true in it's first state.

Since we require the requirements of the tiling to hold only in w', we use a special proposition \$ to mark the first letter after w'. First we define formulas that force the block to follows the roles above.

- $\gamma_1 = \# \wedge \bigwedge_{0 \leq i < n} \mathbf{X}^i\, c_0$ the first block counter value is $000 \ldots 0$.
- $\gamma_2 = (\# \to \bigwedge_{1 \leq i < n} \mathbf{X}^i(\neg\#)) \wedge \mathbf{X}^n\, \# \,\mathbf{U}\, \$$ - after every $\#$ there are n-1 states without $\#$, and then another $\#$.

The following four formulas make sure that the counter (that is encoded by c_0, c_1) value is increased by one every $\#$ (modulo l). We used an additional proposition z that represents the carry.

- $\gamma_3 = (((\# \vee z) \wedge c_0) \to (\mathbf{X}(\neg z) \wedge \mathbf{X}^n\, c_1))\, \mathbf{U}\, \$$
- $\gamma_4 = ((\neg(\# \vee z) \wedge c_0) \to (\mathbf{X}(\neg z) \wedge \mathbf{X}^n\, c_0))\, \mathbf{U}\, \$$
- $\gamma_5(((\# \vee z) \wedge c_1) \to (\mathbf{X}\, z \wedge \mathbf{X}^n\, c_0))\, \mathbf{U}\, \$$
- $\gamma_6((\neg(\# \vee z) \wedge c_1) \to (\mathbf{X}(\neg z) \wedge \mathbf{X}^n\, c_1))\, \mathbf{U}\, \$$

The next two formulas require that the first \$ appear right after w'. I.e., after a line that has t_a at its left position.

- $\gamma_7 = (\neg\$)\, \mathbf{U}\, (\# \wedge \bigwedge_{0 \leq i < n} \mathbf{X}^i\, c_0 \wedge (t_a))$ - No \$ until a tile t_a appear at the left position of a row.
- $\gamma_8 = ((\# \wedge \bigwedge_{0 \leq i < n} \mathbf{X}^i\, c_0 \wedge (\bigvee_{t_a \in \tau_a} t_a)) \to (((\neg\$)\, \mathbf{U}\, (\# \wedge \bigwedge_{0 \leq i < n} \mathbf{X}^i\, c_1)) \wedge (((\# \wedge \bigwedge_{0 \leq i < n} \mathbf{X}^i\, c_1) \to (\mathbf{X}^n\, \$))\, \mathbf{U}\, \$)\, \mathbf{U}\, \$$ - At the last line, \$ appear only after the last letter in the line.

Next, we define the formulas that require a legal tiling. The first requirement of the tiling is that $f(0,0) = t_0$. This requires simply that the first letter of w is t_0. $\gamma_9 = t_0$.

The requirement that a letter from τ_a appear at the left most position of the last row, is simply the requirement that w' is finite. We can require that by $\gamma_{10} = \mathbf{F}\,\$$.

The third requirement is that for every $0 \leq i < l-1$, and $0 \leq j \leq j_a$, we have $(f(i,j), f(i+1,j)) \in H$. Two letters represents horizontal neighbors if they are next to each-other and the first one is not at the end of a row. The letters that at the end of a raw has the highest counter value i.e $11\ldots1$. The formula simply requires that for all blocks that are not at the end of a raw, the current letter and the letter of the next block are in H.

$$\gamma_{11} = ((\# \wedge \neg(\bigwedge_{0 \leq i < n} \overset{i}{\mathbf{X}}\, c_1)) \rightarrow (\bigwedge_{t_1 \in T} (t_1 \rightarrow \overset{n}{\mathbf{X}} \bigvee_{t_2 | (t_1,t_2) \in H} t_2))) \,\mathbf{U}\, \$$$

The last requirement is harder, given a block its vertical neighbor is the next block with the same block counter value. We use auxiliary variables $p_0, p_1, \ldots p_{n-1}$ that capture the block counter value. First we define a formula that requires that the number encoded by $p_0, \ldots p_{n-1}$ is equal to current block counter value.

$$\gamma_{=} = \# \wedge \bigwedge_{0 \leq i < n} ((\overset{i}{\mathbf{X}}\, c_1) \leftrightarrow p_i)$$

Next, we define a formula that requires that if the current block counter value is equal to $p_0 \ldots p_{n-1}$, then the next block with a counter value that is equal to $p_0 \ldots p_{n-1}$ has value t.

$$\gamma_{nextt} = \gamma_{=} \rightarrow \mathbf{X}(\neg\gamma_{=}\, \mathbf{U}\, (\gamma_{=} \wedge t))$$

The next formula require that whenever the current block counter value is equal to $p_0 \ldots p_{n-1}$, then it's letter t_1 and the letter t_2 of it's next vertical neighbor are in V.

$$\gamma_{12} = ((\# \wedge \gamma_{=}) \rightarrow (\bigwedge_{t_1 \in T} (t_1 \rightarrow \bigvee_{t_2 | (t_1,t_2) \in V} \gamma_{nextt_2}))) \,\mathbf{U}\, \$$$

The third requirement of the domino problem requires that for every value of $p_0 \ldots p_{n-1}$, γ_{12} holds. We define the following inductive sequence of formulas:

$$\psi_0 = (\textsf{reject}\ p_0\ \textsf{in}\ \gamma_{12}) \wedge (\textsf{reject}\ \neg p_0\ \textsf{in}\ \gamma_{12})$$

For $0 < i < n$ we have:

$$\psi_i = (\textsf{reject}\ p_i\ \textsf{in}\ \psi_{i-1}) \wedge (\textsf{reject}\ \neg p_i\ \textsf{in}\ \psi_{i-1})$$

Lemma 3. *For every $0 \leq i < n$ the formula ψ_i requires that for all values of $p_0 \ldots p_i$, the formula γ_{12} holds.*

Proof. : We prove by induction on i.

- For the base case: aeject p_0 in γ_{12} requires γ_{12} to hold when $\neg p_0$ holds in all states, and reject $\neg p_0$ in γ_{12} requires γ_{12} to hold when p_0 holds in all states. The formula ψ_0 requires that both options will hold.
- Assume that the lemma holds for $i-1$ then reject p_i in ψ_{i-1} requires ψ_{i-1} to hold when $\neg p_i$ holds in all states, and reject $\neg p_i$ in ψ_{i-1} requires ψ_{i-1} to hold when p_i holds in all states. The formula ψ_i requires that both options will hold. □

Corollary 2. *ψ_{n-1} requires that for every value of $p_0 \ldots p_{n-1}$, formula γ_{12} holds.*

The formula ψ is the conjunction of formulas $\gamma_0, \ldots \gamma_{12}$ and ψ_{n-1}. Formulas $\gamma_0, \ldots \gamma_{12}$ can be represented as DAG with size linear at n. The formulas $\psi_0, \ldots \psi_{n-1}$ can be represented as DAGs with constant size. Thus the size of ψ is linear in n.

We show a linear reduction from the domino problem to the satisfiability of an Reset-LTL formula that is represented as a DAG. Thus we conclude that the satisfiability problem of this logic is EXPSPACE hard.

B Proofs for Section 4

The following lemma complete the proof of Theorem 4.

Lemma 4. *The automaton $\mathcal{A}_\varphi$ accept $L(\varphi')$.*

Proof. First, we prove that for every word w, if w is in $L(\varphi)$, then $\mathcal{A}_\varphi$ accept w. Let w be a word in $L(\psi')$. Then either $w \in L(\psi)$ or there is a prefix w' of w and an infinite word w'' such that b is true in the last letter of w' and $w' \cdot w'' \in L(\psi)$. Assume first that w is in $L(\psi)$. Then, w is accepted by $\mathcal{A}_\psi$, thus it is accepted by $\mathcal{A}_\varphi$. Assume now that there is a prefix w' of w and an infinite word w'' such that b is true in the last letter of w' and $w' \cdot w'' \in L(\psi)$. Since $w' \cdot w''$ is in $L(\psi)$, $\mathcal{A}'_n$ accepts $w' \cdot w''$. Let ρ be an accepting run of $\mathcal{A}'_n$ over $w' \cdot w''$. By the definition of $\mathcal{A}_{fin}$, if $w_i \not\models b$ then $\rho_{i+1} \in \delta(\rho_i, w_i)$. Let j be the smallest number such that $w_j \models b$, since b is true in the last letter of w', j is finite. Then, the prefix of ρ until ρ_j is a run of $\mathcal{A}_{fin}$ on w' that reaches **true**. Thus, every extension of w' in particular w is accepted by $\mathcal{A}_{fin}$ and thus by $\mathcal{A}_\varphi$.

Next, we prove that if w is accepted by $\mathcal{A}_{\psi'}$, then w is in $L(\varphi)$. We distinguish between two cases:

1. If w is accepted by $\mathcal{A}_\psi$ then w is in $L(\psi)$ thus it is in $L(\psi')$.
2. Otherwise, $\mathcal{A}_{fin}$ has a finite accepting run ρ on w that reaches **true**. Let w' be the prefix that match ρ. The construction of $\mathcal{A}_{fin}$ implies that b is true in the last letter of w', and that ρ is also a run of $\mathcal{A}'_n$. Let s be the last state in ρ and let s' be a successor of s on the last letter of w' at $\mathcal{A}'_n$. Since s' is a state of $\mathcal{A}'_n$, there is an accepting run ρ'' of $\mathcal{A}_n$ starting at s'. Let w'' be the word accepted by ρ'', then the run $\rho \cdot \rho''$ is an accepting run of $\mathcal{A}'_n$ on $w' \cdot w''$. This implies that $w' \cdot w''$ is in $L(\psi)$. Thus there is a prefix w' of w such that b is true in the last letter of w' and that can be extended to a word $w' \cdot w''$ in $\text{Ł}(\psi)$. This implies that w is in $L(\varphi)$. □

B.1 Lower bound

We now prove Lemma 1 showing that every ABW that except ψ_n^k has at least $exp(k, n)$ states.

We prove that Every NBW that except ψ_n^k has at least $exp(k+1, n)$ states. Since there exists a translation of NBW to ABW with a single exponential blowup [11], this implies the lemma. Let $\mathcal{A} = \langle S, S_0, \delta, F\rangle$ be an NBW that accepts $L(\psi_n^k)$. Since we ignore some of the propositions in some of the cells, there are many actual words w' that represents a single word w of length $exp(k, n)$. Assume to the contrary that $|S| < exp(k+1, n)$. For every actual word w' that represents a word w of length $exp(k, n)$ we define S'_w to be the set of states that $\mathcal{A}$ reaches after running on w' in an accepting run. $\mathcal{A}$ accepts all actual words that represents words of the form $w \cdot w$, thus for every w', $S'_w \neq \emptyset$. Since $|S| < 2^n$, there are two actual words w'_1 and w'_2, which represent different words w_1 and w_2 respectively, such that $S'_{w_1} \cap S'_{w_2} \neq \emptyset$. Let s be a state in $S'_{w_1} \cap S'_{w_2}$. $\mathcal{A}$ accept $w'_1 w'_1 \Sigma^\omega$, thus there is an accepting run of $\mathcal{A}^{(s)}$ on the word $w'_1 \Sigma^\omega$. This implies that the run of $\mathcal{A}$ that reach s on w'_2 and then continue on $w'_1 \Sigma^\omega$ is accepting. Thus $\mathcal{A}$ accept a word $w'_2 \cdot w'_1$ that represents a word $w_2 \cdot w_1$, we reach a contradiction. □

B.2 Reduction from the domino problem to Abort-LTL satisfiability

Given a finite version of the domino problem $\langle T, V, H, t_0, t_a, l = exp(k, n)\rangle$ we construct a k levels formula φ_k, using Γ^i and Θ^i sets in the same way that we used them in Section 4. Such that φ_k is satisfiable if and only if, there is an $l \times m$ tiling for $\langle T, V, H, t_0, t_a, l\rangle$. Each letter is represented by a $(k-1)$-block and each row is represented by k-block. We use the proposition \$ to mark the first cell after the $l \cdot m$ length word. Note that m is unbound, thus we require \$ to first appear after a k-block that starts with t_a.

– The requirement that $f(0,0) = t_0$ is simply the requirement that the first state is labelled by $\varphi_0 = t_0$.
– The requirement that $f(0,m) = t_k$ is actually the requirement that for some finite m, $f(0,m) = t_k$ and the cell right after this row is marked with \$. The first tile in a row is represented by the first $(k-1)$-block in a k-block, i.e., a $(k-1)$-bloke with position $00\ldots0$. We use the @ proposition to mark a t_a that appear at the beginning of a row. The first formula require that the first @ appear on a tile t_a at the beginning of a k-block.

$$\varphi_{a1} = ((\neg @)\,\mathbf{U}\,(@ \wedge (\#_{k-1} \wedge ((\#_{k-2} \rightarrow c_0^{k-1})\,\mathbf{U}\,\mathbf{X}\,\#_{k-1})))$$

Next, we require that such @ eventually appears and that the first \$ appear right after the k-block that contains the first @.

$$\varphi_{a2} = \mathbf{F}\,@ \wedge ((\neg @ \wedge \neg \$)\,\mathbf{U}\,(@ \wedge \mathbf{X}((\neg \#_k \wedge \neg \$)\,\mathbf{U}\,(\#_k \wedge \$))))$$

– The requirement that for every $0 \leq i < l-1$, and $0 \leq j < m$, we have $(f(i,j), f(i+1,j)) \in H$ is also simple: The formula

$$\varphi_{h1} = \bigwedge_{t_i \in T} ((\#_{k-1} \wedge t_i) \rightarrow \mathbf{X}((\neg \#_{k-1})\,\mathbf{U}\,((\#_{k-1} \wedge \bigvee_{t_j | (t_i,t_j) \in H} t_j)))$$

requires that if the current letter is t_i the the next letter t_j should satisfy $(t_i,t_j) \in H$. This should hold in every letter except the last letters in every raw. Notice, that the last $(k-1)$-block in every row has a $11\ldots1$ $(k-2)$-block position. Thus the formula for the second requirement is:

$$\varphi_{h2} = ((\neg(\#_{k-1} \wedge ((\#_{k-2} \rightarrow c_1^{k-1})\,\mathbf{U}\,\mathbf{X}\,\#_{k-1}))) \rightarrow \varphi_{h1})\,\mathbf{U}\,\$$$

Notice, that since $|T|$ is a constant, $|\phi_{h2}| = O(1)$.
– The requirement that for every $0 \leq i < m$, and $0 \leq j \leq l$, we have $(f(j,i), f(j,i+1)) \in V$ is a bit more complicated. We use formulas similar to the formulas of Θ^i to require that something is true in the next place with the same $(k-1)$-block position (meaning the same position in the next raw). We use the formula $\theta_{=}^{k-1}$ that requires the current $(k-1)$-block to be equivalent to the $(k-1)$-block that starts after $\$_k$. For each tile t_i we define the formula

$$\varphi_{nxt_i} = \theta_{=}^{k-1} \wedge ((\neg \#_k)\,\mathbf{U}\,(\#_k \wedge (((\#_{k-1} \wedge \theta_{=}^{k-1}) \rightarrow t_i)\,\mathbf{U}\,\mathbf{X}\,\#_k))$$

Then we define

$$\varphi_{nextt_i} = \varphi_{nxt_i} \text{ abort on } \$_{k-1}$$

that requires the tile with the same $(k-1)$-block position on the next raw (k-block) to be labelled by t_i. The rest is similar to the horizontal case: The formula

$$\varphi_{v1} = \bigwedge_{t_i \in T} (t_i \rightarrow \bigvee_{t_j | (t_i,t_j) \in V} \varphi_{nextt_j})$$

that requires that the next vertical neighbor is in V. This should hold only until the last raw i.e., until the first @. Thus

$$\varphi_{v2} = \varphi_{v1}\,\mathbf{U}\,@$$

Finally we define: φ_k to be the conjunction of the formulas above. The size of φ_k is $O(4^k)$, which is less then the representation of l for $k > 2$ thus the reduction is sub linear in the input of the problem. It is easy to see that every trace that satisfies φ_k represents a legal tile, and that every legal tile can be represented by a trace that satisfies φ_k. Thus, the complexity of the satisfiability of Abort-LTL is non-elementary hard.

As for model-checking for Abort-LTL, the problem of satisfiability of φ_k can be easily reduced to a model-checking problem of Abort-LTL. Since the number of atomic proposition of φ_k is linear in k, we construct an NBW $\mathcal{A}$ with one state that contains all infinite traces over the atomic propositions of φ_k. It easy to see that φ_k is satisfiable if and only if $\mathcal{A} \models \varphi_k$. Thus the complexity of model-checking of Abort-LTL is nonelementary hard.
